Abstract

A rapid microwave synthesis route for the fabrication of ZnIn$_2$S$_4$ powder and ZnIn$_2$S$_4$/WS$_2$ composite is presented. Firstly, effect of different sulfur sources – thioacetamide and L-cysteine – on the physicochemical properties and photocatalytic H$_2$ production of the synthesized ZnIn$_2$S$_4$ were investigated. It was found that well-defined flower-like ZnIn$_2$S$_4$ microspheres obtained from L-cysteine facilitated a relatively higher H$_2$ production rate. Then, different loadings of WS$_2$ were introduced into the well-defined flower-like ZnIn$_2$S$_4$ microspheres aiming to improve its photocatalytic H$_2$ production. Compared to the pure ZnIn$_2$S$_4$ and WS$_2$, all ZnIn$_2$S$_4$/WS$_2$ composite photocatalysts exhibited enhanced photocatalytic H$_2$ production in the presence of Na$_2$S/Na$_2$SO$_3$ as sacrificial reagents under UV-visible irradiation, where the ZnIn$_2$S$_4$/WS$_2$-40%wt composite had the highest photocatalytic activity. For this material, 293.3 and 76.6 µmol h$^{-1}$ g$^{-1}$ of H$_2$ gas were produced under UV-visible and visible light irradiation respectively. In addition, the photoreduction activity of hexavalent chromium (Cr(VI)) by the ZnIn$_2$S$_4$/WS$_2$-40%wt was also investigated under visible light irradiation and it was observed that 98.5% of Cr(VI) was reduced within 90 min at pH 4.

Keywords: ZnIn$_2$S$_4$/WS$_2$, Microwave synthesis, Heterostructure, H$_2$ production, Cr(VI) reduction
1. Introduction

Photocatalysis has attracted considerable as a sustainable approach for solving environmental and energy problems that face society as a whole. Production of hydrogen from photocatalytic water splitting is regarded as the promising strategies for conversion of solar energy to chemical energy. In addition, the elimination of heavy metal ions from wastewater is also considered to be an important research target for photocatalysis. Growth of new technologies based on photocatalysts for water splitting and hexavalent chromium (Cr(VI)) reduction using semiconductors has evolved from the initial utilization of metal oxide semiconductors, to second-generation semiconductor involving doped metal oxides as well as two-dimensional (2-D) semiconductors. Semiconductors such as TiO$_2$, ZnO and CdS are able to utilize photons under ultraviolet radiation which makes up 4% of the solar incident light. Doping TiO$_2$ with a third element such as C, S or metal doping can improve the solar light utilization in the visible light region. The investigation of ultrathin 2-D semiconductors with superior activity for enhancing photon absorption and electron-hole utilization has recently attracted significant interest as a new generation of photocatalysts. Layered-structure semiconductors with nanolayer thickness, in principle, possess a high surface area for photon absorption, substrate adsorption and generation of highly active oxidizing species. Nevertheless, this principle is based on the ability of the semiconductor to take full advantage of the photons in the entire solar spectrum, to efficiently separate the photo-generated charge carriers and finally remain robust and stable to drive the water oxidation/reduction reaction. Improved visible-light-driven photocatalysts are now required to promote the efficiency of solar energy conversion.

ZnIn$_2$S$_4$, the only member of the AB$_2$X$_4$ family of semiconductors with a single-layered structure, has attracted interest because of its potential applications in the fields of charge storage, thermoelectricity, hydrogen production and as photodetectors. ZnIn$_2$S$_4$ is an
ideal candidate as an active photocatalyst to drive photocatalytic water splitting\textsuperscript{13} and photocatalytic Cr(VI) reduction\textsuperscript{14} in the visible light region due to its photochemical stability and narrow band gap energy (2.75 eV). In addition, the layered structure of ZnIn\textsubscript{2}S\textsubscript{4} can increase the exposure of the interlayer sulfur atom which increases the interaction with oxygen as the active photo-generated carrier scavenger.\textsuperscript{15} However, its photocatalytic efficiency is still under scrutiny with concern about its narrow band gap that can contribute to fast recombination of photo-generated charge carriers. The charge carrier recombination is classified into two types: bulk recombination and surface recombination.\textsuperscript{16} Decreasing the bulk recombination can be achieved by fabricating the ZnIn\textsubscript{2}S\textsubscript{4} 2-D microstructure which in principle can shorten the distance for the charge carrier to travel to its surface and also can reduce the impurities and defects in the ZnIn\textsubscript{2}S\textsubscript{4} crystal.\textsuperscript{17} Modification of the ZnIn\textsubscript{2}S\textsubscript{4} by introducing surface defects, constructing heterojunction structure, and co-doping with metals can prevent surface recombination.\textsuperscript{18 19 20} Doping transition metals or noble metals on the surface of ZnIn\textsubscript{2}S\textsubscript{4} can improve the photocatalytic efficiency of the ZnIn\textsubscript{2}S\textsubscript{4} but the light absorption efficiency is limited particularly at high metal loadings.\textsuperscript{21 22} In addition, noble metals are expensive and this can limit their wider application as components of photocatalysts.\textsuperscript{18 23} Combination of ZnIn\textsubscript{2}S\textsubscript{4} with another semiconductor is therefore a feasible alternative to suppress the recombination of the photo-generated charge carriers. For example, ZnIn\textsubscript{2}S\textsubscript{4}/CdS, ZnIn\textsubscript{2}S\textsubscript{4}/In\textsubscript{2}S\textsubscript{3}, ZnIn\textsubscript{2}S\textsubscript{4}/K\textsubscript{2}La\textsubscript{2}Ti\textsubscript{3}O\textsubscript{10}, ZnIn\textsubscript{2}S\textsubscript{4}/CdIn\textsubscript{2}S\textsubscript{4} have all shown efficacy.\textsuperscript{24 25 26 27} The previous studies have shown that transition metal dichalcogenides (TMDs) such as MoS\textsubscript{2}, MoSe\textsubscript{2} and WS\textsubscript{2} are efficient co-catalysts for improving photocatalytic H\textsubscript{2} production and heavy metal pollutants removal.\textsuperscript{28 29 30 31 32} Among these TMDs, WS\textsubscript{2} is an effective candidate for solar energy conversion due to its narrow band gap energy, a less electronegative valence band, a high reducing activity of conductive band, and a strong W-S bond.\textsuperscript{33} In addition, it is an important material for a wide range of applications including catalysis, batteries and optical devices.\textsuperscript{33 34}
As well as an active component in many hydrogenation reactions such as hydro-
denitrogenation and hydro-desulfurization.\textsuperscript{36,37}

As the conduction band (C\textsubscript{B}) of WS\textsubscript{2} is less negative than that of ZnIn\textsubscript{2}S\textsubscript{4}, a directional electron transfer from the C\textsubscript{B} of ZnIn\textsubscript{2}S\textsubscript{4} to the C\textsubscript{B} of WS\textsubscript{2} and a migration of the photo-
generated holes in the valence band (V\textsubscript{B}) in the opposite way can be enabled.\textsuperscript{38,39} Therefore, WS\textsubscript{2} is a potential co-catalyst for enhancing the photocatalytic activity of ZnIn\textsubscript{2}S\textsubscript{4} since the charge separation would be promoted and the charge recombination would be suppressed.

Herein, we reported the microwave synthesis of flower-like ZnIn\textsubscript{2}S\textsubscript{4} microspheres and ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} composite for photocatalytic applications. This method was chosen in this work because the interaction between a microwave radiation and polar molecules in a reaction system offers a homogeneous heating with fast reaction rate as compared to the conventional heating methods. Therefore, the desired materials with high purity, high crystallinity, and uniform shape and size can be produced with a short time period and reduced processing temperature, leading to a relatively low energy demand for materials production.\textsuperscript{41} In this work, well-defined flower-like ZnIn\textsubscript{2}S\textsubscript{4} microspheres were first synthesized using an appropriate sulfur source for H\textsubscript{2} production from photocatalytic water splitting under UV-visible light irradiation. Then, the ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} composites with different loading amounts of WS\textsubscript{2} were fabricated in an attempt to enhance the H\textsubscript{2} production rate. In addition, recyclability of the ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} photocatalyst was also assessed for its practical use. Furthermore, potential use of the ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} photocatalyst for Cr(VI) photoreduction – a model of heavy metal ions – was also investigated. Possible photocatalytic mechanisms for enhanced photocatalytic activities of the ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} heterojunction were also proposed.
2. Materials and methods

2.1. Preparation of photocatalysts

All the chemicals were analytical grade and used without further purification as they were received. In a typical synthesis, ZnCl$_2$ (2.0 mmol), InCl$_3$·4H$_2$O (4.0 mmol) and a sulfur source (L-cysteine or thioacetamide, 10.0 mmol) were dissolved in de-ionized water (20.0 mL). After constant stirring for 20 min, the solution was transferred into a dissolution vessel with a capacity of 50.0 mL. The vessel was sealed and exposed to microwave radiation in a microwave oven operated at 100 W for 1 h and then naturally cooled to room temperature. Finally, the dark green yellow powder was separated from the mother liquor by a vacuum filtration, then washed with de-ionized water several times and dried (80 °C, 24 h).

To synthesize ZnIn$_2$S$_4$/WS$_2$ composites, the synthesized ZnIn$_2$S$_4$ and commercial WS$_2$ were dispersed in de-ionized water (20 mL) with vigorous stirring. The solution was then transferred into a dissolution vessel with a capacity of 50.0 mL. The vessel was sealed and exposed to microwave radiation in a microwave oven operated at 100 W for 1 h and then naturally cooled to room temperature. Finally, a dark-green powder was separated from the mother liquor by centrifuged and dried (80 °C, 24 h). The composites with different loading amounts of WS$_2$ were denoted as ZIS/WS-x%, where the x represents 20, 30, 40, 50, 60 and 80%wt of WS$_2$. In addition, the ZnIn$_2$S$_4$/WS$_2$-40%wt composite was also prepared by a physical grinding without the microwave treatment for comparison.

2.2. Characterization

X-ray diffraction (XRD) patterns were recorded by a Rigaku Miniflex II X-ray diffractometer, using a CuK$_\alpha$ radiation source (40 kV and 40 mA) and Ni attenuator. UV-visible diffuse reflectance spectra (UV-visible DRS) of the samples were obtained using an Agilent Technologies, Cary Series UV-visible spectrophotometer. The wavelength scans were
collected in the range of 200-800 nm, at a scan rate of 150 nm/min. Brunauer-Emmett-Teller (BET) surface areas were determined by N\textsubscript{2} adsorption at \(-196 \, ^\circ\text{C}\) using a Quantachrome Quadrasorb-evo instrument. The samples were prepared by removing physically adsorbed water at 120 \, ^\circ\text{C} for 3 h under vacuum. Scanning electron microscopy (SEM) images were obtained on TESCAN MAIA3 equipped with an Oxford Instruments X-Max\textsuperscript{N} 80 energy dispersive X-ray (EDX) detector. The samples were mounted on a Carbon Lite adhesive disk attached to an aluminium stub. X-ray photoelectron spectroscopy (XPS) was analyzed using a Kratos Axis Ultra DLD system with a monochromatic Al K\textalpha X-ray source operating at 120 W and analyzer pass energies of 160 eV. The XPS data were analyzed using Casa XPS software. Photoluminescence (PL) spectra were examined by an Avantes AvaSpec-2048TEC-USB2 photoluminescence spectrometer with an excitation wavelength of 590 nm.

Electrochemical impedance spectroscopy (EIS) and Mott-Schottky analysis were performed using a three-electrode electrochemical system. A working electrode was fabricated as follows, a certain amount of the photocatalyst (0.10 g) was dispersed in a mixture of isopropanol and de-ionized water (40:20 \%v/v) by ultrasonic treatment. The dispersion was dropped on a fluorine-doped tin oxide (FTO) coated glass with a fixed area of 1x1 cm\textsuperscript{2}. After evaporation, the photocatalyst was attached to the FTO glass surface. For counter and reference electrodes, a platinum (Pt) plate and Ag/AgCl were used, respectively. Na\textsubscript{2}SO\textsubscript{4} aqueous solution (0.1 M) was used as an electrolyte solution. The Autolab Potentiostat/galvanostat (PGSTAT128N, Metrohm Siam Ltd.) was used for all the tests. The EIS spectra, measured at a frequency range of alternating current was 0.1 Hz - 100 kHz at 1.5 V, were fitted to an appropriate electric analog by the Nova 2.1.3 software. The Mott–Schottky plots were measured at a frequency of 100 Hz. The following equation was used to convert the measured potential vs. Ag/AgCl to the NHE; \(E_{\text{NHE}} = E_{\text{Ag/AgCl}} + E_{\text{Ag/AgCl}}^0\), where \(E_{\text{Ag/AgCl}}^0\) (3.0 M KCl) = 0.21 V at 25 \, ^\circ\text{C}.
2.3. Photocatalytic reactions

The H\textsubscript{2} production experiment was carried out in a Pyrex flask (150 mL) fitted with a purge line and a septum for sampling. Reactions were carried out with a suspension of photocatalyst (0.10 g) in a sacrificial reagent which consisted of 0.35 M Na\textsubscript{2}S mixed 0.25 M Na\textsubscript{2}SO\textsubscript{3} solution (40 mL) and de-ionized water (60 mL). Before the reaction, the mixture was purged with argon gas for 30 min to remove dissolved air. The mixture was illuminated with a 150 W Xe arc lamp (Oriel Model 66084, light source 10 cm from the vessel) under constant stirred. Gas samples (0.5 mL) were taken periodically and analyzed for H\textsubscript{2} using a gas chromatograph (PerkinElmer Clarus 480). The apparent quantum yields (AQY) of the pure ZnIn\textsubscript{2}S\textsubscript{4} and composite photocatalysts for the H\textsubscript{2} production were calculated according to the following equation \textsuperscript{42}:

\[
\text{AQY} (\%) = \frac{2 \times \text{number of evolved H}_2 \text{ molecules}}{\text{number of incident photon}} \times 100
\]

where the light intensity is 119.43 mW/cm\textsuperscript{2} and the light spot area is 12.56 cm\textsuperscript{2} with a 400 nm band pass filter. The “2” value means that two electrons are necessary for the formation of one hydrogen molecule, and, correspondingly, it is required that two photons interact with the photocatalyst.

The photoreduction of Cr(VI) was performed under a suspension of the photocatalyst (0.10 g) in a K\textsubscript{2}Cr\textsubscript{2}O\textsubscript{7} solution (10 ppm, 200 mL) and the pH of reaction suspension was adjusted by adding 1 M HCl or 1 M NH\textsubscript{4}OH. The suspension was placed in the dark and stirred for 30 min to achieve the adsorption-desorption equilibrium. After that, the mixture was irradiated under a 50 W LED white light with a fixed distance from the light source to the reactor at 8.5 cm. During the photocatalytic reaction, the suspension (5 mL) was sampled every 30 min. Then, 1,5-diphenylcarbazide and H\textsubscript{2}SO\textsubscript{4} were added into the sampling to form a Cr(VI)-diphenylcarbazide complex, which gives a reddish-purple color. Finally, the complex
solution was measured at its maximum absorption wavelength of 532 nm by using a UV-visible spectrophotometer (UV-1800 Shimadzu). The photoreduction efficiency was calculated using the following equation: 

\[ \% \text{Photoreduction efficiency} = \left( \frac{C_0 - C}{C_0} \right) \times 100 \]

where \( C_0 \) and \( C \) are the concentrations of the Cr(VI) complex when adsorption-desorption equilibrium is achieved and after light irradiation, respectively. A blank experiment (without any photocatalyst) was also carried out under the same conditions. The apparent quantum yields (AQY) of the pure ZnIn\(_2\)S\(_4\) and composite photocatalysts for the Cr(VI) reduction were calculated according to the following equation \(^{43}\):

\[ \text{AQY} (%) = \frac{3 \times \text{number of reduced Cr(VI) ions}}{\text{number of incident photon}} \times 100 \]

where the light intensity is 54.95 mW/cm\(^2\) and the light spot area is 6.25 cm\(^2\) with a 400 nm band pass filter. The “3” value means that three electrons are necessary for the formation of one Cr(III) ion, and, correspondingly, it is required that three photons interact with the photocatalyst.

3. Results and discussion

3.1. Influence of the sulfur source on the physicochemical properties and photocatalytic activity of ZnIn\(_2\)S\(_4\)

The XRD patterns of the synthesized powders obtained from the two different sulfur sources (Fig. 1a) provide an information on their crystal structure and crystallinity. The main diffraction reflections are observed at 2\(\theta\) of 21.2°, 27.9°, 30.1°, 39.9°, 47.3°, 51.8° and 55.5°, respectively representing the (006), (102), (104), (108), (110), (116) and (202) crystal planes of hexagonal ZnIn\(_2\)S\(_4\) (JCPDS database no. 01-072-0773). ZnIn\(_2\)S\(_4\) synthesized using the microwave synthesis method are well-crystallized with no characteristic reflections of possible impurities such as ZnS, In\(_2\)S\(_3\) or the corresponding metal oxides. The crystallite size of the
ZnIn$_2$S$_4$ particles was calculated from the (110) reflection by applying the Debye-Scherrer equation. The calculated crystallite size of the ZnIn$_2$S$_4$ synthesized using L-cysteine is smaller than that using thioacetamide as presented in Table 1.

**Fig. 1.** a.) XRD patterns, and SEM images of the ZnIn$_2$S$_4$ powders synthesized using b.) L-cysteine (ZIS-L-cys) and c.) thioacetamide (ZIS-TAA) as sulfur sources.

**Table 1** Comparison of calculated crystallite size, surface area, absorption edge and band gap energy of the ZnIn$_2$S$_4$ synthesized using different sulfur sources.

SEM images of ZnIn$_2$S$_4$ synthesized using L-cysteine and thioacetamide are presented in Fig. 1b and 1c, respectively. ZnIn$_2$S$_4$ synthesized using L-cysteine has well-defined flower-like microspheres ranging from 3 to 6 µm in diameter. Such microspheres comprise interconnecting nanosheets, resulting in a porous structure on the surface of the ZnIn$_2$S$_4$ microspheres. Using thioacetamide as the sulfur source, the ZnIn$_2$S$_4$ particles exhibit accumulated curled nanosheets on their surface can be observed. The BET surface area analysis of the ZnIn$_2$S$_4$ particles (summarized in Table 1) indicates that the ZnIn$_2$S$_4$ particles synthesized using L-cysteine show
relatively higher surface area (46 m$^2$/g) than those synthesized using thioacetamide (28 m$^2$/g). In addition, elemental analysis reveals that the mole ratio of Zn:In:S is 1:2.3:4.08, in a good agreement with the stoichiometry of ZnIn$_2$S$_4$.

The formation of the hexagonal ZnIn$_2$S$_4$ flower-like microspheres, reported by Chen et al.\cite{45}, occurs via two main steps: (i) the formation of hexagonal ZnIn$_2$S$_4$ nuclei through the reaction among the starting reagents and (ii) the intrinsic anisotropic growth of the produced ZnIn$_2$S$_4$ nuclei into an hexagonal lamellar structure. Subsequently, the flower-like microspheres are formed from the self-assembly of the nanosheets. In this research, the difference in the microstructure of the ZnIn$_2$S$_4$ microspheres is possibly related to the molecular structures of L-cysteine and thioacetamide, and the rate of S$^{2-}$ ions released during the microwave heating process. Although both L-cysteine and thioacetamide can coordinate with inorganic cations to form metal-ligand complexes, the functional groups of L-cysteine molecule (-NH$_2$, -COOH and -SH) have a stronger affinity to coordinate with the metal ions comparing with the functional groups of thioacetamide (-NH$_2$ and -SH).\cite{46,47} Consequently, the rate of S$^{2-}$ ions released from the metal-L-cysteine complex is slower than that from the metal-thioacetamide complex.\cite{48} As a result, the hexagonal ZnIn$_2$S$_4$ nuclei are slowly produced and consequently well-crystallized ZnIn$_2$S$_4$ nanosheets are gradually formed. Finally, accelerated by microwave heating, the adjacent nanosheets are self-assembled to form flower-like ZnIn$_2$S$_4$ microspheres. In addition, the steric hindrance of L-cysteine molecules can prevent the accumulation of nanoplate-clusters on the surface of the ZnIn$_2$S$_4$ microspheres, enabling the construction of open pore structure on the ZnIn$_2$S$_4$ microspheres surface.

The surface electronic states and chemical composition of the ZnIn$_2$S$_4$ microspheres synthesized using L-cysteine were investigated by XPS analysis and are shown in Fig. 2a. The high-resolution spectrum of Zn 2p shows the binding energy at 1022.03 eV and 1045.08 eV, which are ascribed to Zn 2p$_{3/2}$ and Zn 2p$_{1/2}$ respectively. The In 3d spectrum of shows two peaks
centered at the binding energy of 445.08 eV (In 3d\textsubscript{5/2}) and 452.63 eV (In 3d\textsubscript{3/2}). The spectrum of S 2p indicates that the signal can be convoluted into two peaks. One is located at 161.88 eV (S 2p\textsubscript{3/2}) and the other at 162.88 eV (S 2p\textsubscript{1/2}). These binding energy values correspond to the chemical valence states of Zn\textsuperscript{2+}, In\textsuperscript{3+} and S\textsuperscript{2-}, respectively.\(^{49}\) The UV-visible DRS spectra of ZnIn\textsubscript{2}S\textsubscript{4} (Fig. 2b) show an absorption edge in the visible region (located around 450-500 nm). Band gap energy (Table 1), calculated from the absorption edges, of the ZnIn\textsubscript{2}S\textsubscript{4} synthesized using L-cysteine (2.81 eV) is larger than that synthesized using thioacetamide (2.48 eV).

**Fig. 2.** a.) High resolution XPS spectra of Zn 2p, In 3d and S 2p for the ZnIn\textsubscript{2}S\textsubscript{4} powders synthesized using L-cysteine; b.) UV-visible DRS spectra of the ZnIn\textsubscript{2}S\textsubscript{4} synthesized using different sulfur sources and c.) H\textsubscript{2} production rate during 3 h reaction on the ZnIn\textsubscript{2}S\textsubscript{4} photocatalyst synthesized using different sulfur sources under Xenon light irradiation.

The photocatalytic activity for H\textsubscript{2} production of the ZnIn\textsubscript{2}S\textsubscript{4} photocatalyst was evaluated using 0.35 M Na\textsubscript{2}S and 0.25 M Na\textsubscript{2}SO\textsubscript{3} mixed aqueous solution under UV-visible irradiation.
for 3 h. As shown in Fig. 2c, the H\textsubscript{2} production rate of the ZnIn\textsubscript{2}S\textsubscript{4} photocatalyst synthesized using L-cysteine (145.3 \(\mu\)mol h\textsuperscript{-1} g\textsuperscript{-1}) is higher than that synthesized using thioacetamide (81.6 \(\mu\)mol h\textsuperscript{-1} g\textsuperscript{-1}). This we consider is related to the well-defined flower-like ZnIn\textsubscript{2}S\textsubscript{4} microspheres with the open pore structure can permit multi-reflection of an incident light in its structure which facilitates a longer life-time of the incident light, thereby more electron-hole pairs can be generated.\textsuperscript{50} Moreover, the higher surface area of the ZnIn\textsubscript{2}S\textsubscript{4} photocatalyst can offer more active sites exposed to the reactants during the photocatalytic processes, as a result, the photocatalytic reaction can occur more easily.\textsuperscript{51} In addition, the wider band gap energy of the well-defined flower-like ZnIn\textsubscript{2}S\textsubscript{4} microspheres would reduce the recombination process of the photo-generated electrons and holes which is available for the photocatalytic reactions.\textsuperscript{52} As discussed above, the ZnIn\textsubscript{2}S\textsubscript{4} synthesized using L-cysteine was chosen to combine with WS\textsubscript{2} in order to improve photocatalytic activity in the production of H\textsubscript{2}.

3.2. Influence of the loading amount of WS\textsubscript{2} on the physicochemical properties of ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} composite

The ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} composites with different loading amounts of WS\textsubscript{2} were prepared by the microwave synthesis method. The XRD patterns (Fig. 3a) of the ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} composite samples with 20, 40, 60, and 80%wt of WS\textsubscript{2}, show the main diffraction reflections of a hexagonal ZnIn\textsubscript{2}S\textsubscript{4} structure (JCPDS database no.01-072-0773) with the additional reflections at 14.3°, 33.7°, 39.5° and 58.4° which correspond to a hexagonal WS\textsubscript{2} structure (JCPDS no.00-008-0237). This result implies that the introduction of WS\textsubscript{2} through microwave heating treatment does not affect the hexagonal ZnIn\textsubscript{2}S\textsubscript{4} crystal structure. In addition, the diffraction reflection intensity of WS\textsubscript{2} is gradually increase with increasing amounts of WS\textsubscript{2} in the composites, while the diffraction reflection intensity of ZnIn\textsubscript{2}S\textsubscript{4} is gradually decrease. The UV-visible DRS spectra of ZnIn\textsubscript{2}S\textsubscript{4}, WS\textsubscript{2}, and ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2}-40%wt are shown in Fig. 3b.
Compared to ZnIn$_2$S$_4$, the absorption edge of the ZnIn$_2$S$_4$/WS$_2$-40%wt composite shifts to a higher wavelength due to the presence of WS$_2$. This suggests that the ZnIn$_2$S$_4$/WS$_2$ composite has improved visible light response after introducing WS$_2$, thereby promoting a generation of electron-hole pairs. Therefore, the enhanced photocatalytic activity is expected from the ZnIn$_2$S$_4$/WS$_2$ heterostructure under visible light irradiation.

**Fig. 3.** a.) XRD patterns and b.) UV-visible DRS spectra of the synthesized powders.
Fig. 4 shows the XPS spectrum of the ZnIn$_2$S$_4$/WS$_2$-40%wt composite compared with ZnIn$_2$S$_4$ and WS$_2$. In Fig. 4(a-c), the XPS spectra of the ZnIn$_2$S$_4$/WS$_2$-40%wt composite show binding energy of Zn 2p, In 3d and S 2p, corresponding to ZnIn$_2$S$_4$. The XPS spectra of W 4f are shown in Fig. 4d. The binding energy at 32.58, 34.78 and 38.28 eV correspond to W 4f$_{7/2}$, W 4f$_{5/2}$ and W 4f$_{3/2}$, respectively. These results confirm the coexistence of ZnIn$_2$S$_4$ and WS$_2$ in the composite. In addition, the binding energies of Zn 2p, In 3d and S 2s are shifted to higher values after introducing WS$_2$. While, the binding energies of W 4f are slightly shifted to lower values in comparison to pure WS$_2$. These indicate that the chemical environments of Zn$^{2+}$, In$^{3+}$, W$^{4+}$ and S$^{2-}$ ions in the ZnIn$_2$S$_4$ and WS$_2$ structures are changed, showing a chemical interaction at the contact interface of the ZnIn$_2$S$_4$/WS$_2$ heterostructure rather than a physical contact between the two separate ZnIn$_2$S$_4$ and WS$_2$ materials.

Fig. 4. High resolution XPS spectra of a.) Zn 2p, b.) In 3d, c.) S 2p and d.) W 4f of the ZnIn$_2$S$_4$/WS$_2$-40%wt composite compared with ZnIn$_2$S$_4$ and WS$_2$. 
SEM images of the ZnIn$_2$S$_4$, WS$_2$, and ZnIn$_2$S$_4$/WS$_2$-40%wt powders are presented in Fig. 5a-5c. The SEM image of the ZnIn$_2$S$_4$/WS$_2$-40%wt composite (Fig. 5c) reveals that the nanoparticles with the average diameter of about 80 nm of the WS$_2$ (Fig. 5b) are dispersed on the surface of the flower-like ZnIn$_2$S$_4$ microspheres (Fig. 5a). The TEM images (Fig. 5d) indicate that the WS$_2$ nanoparticles are closely attached to the flower-like ZnIn$_2$S$_4$ microsphere in which the microsphere are developed by stacking of multiple nanosheet layers with 1.68 nm thickness. The HRTEM image of the WS$_2$ nanoparticle in the composite reveals the 0.62 nm lattice spacing that can be assigned to the (002) plane of hexagonal WS$_2$, while the ZnIn$_2$S$_4$ nanosheet in the composite (Fig. 5d) reveals the 0.32 nm lattice fringe which corresponds to the (102) plane of hexagonal ZnIn$_2$S$_4$. The EDX spectrum of the ZnIn$_2$S$_4$/WS$_2$-40%wt composite (Fig. 5e) reveals the characteristic peaks of Zn, In, S and W elements, which evidently indicates the presence of both ZnIn$_2$S$_4$ and WS$_2$ in the composite. Notably, the signals of Au and O elements come from the coated gold and environment, respectively. The corresponding EDX elemental mapping (Fig. 5e) shows that the Zn, In, S and W elements are uniformly distributed throughout the composite material. These results clearly show that the ZnIn$_2$S$_4$/WS$_2$ heterostructure with intimate and efficient interfacial contact was successfully formed after the microwave heat treatment.
Fig. 5. a.)-c.) SEM images of the ZnIn$_2$S$_4$, WS$_2$, and ZnIn$_2$S$_4$/WS$_2$-40%wt powders, b.) TEM and HRTEM images of the ZnIn$_2$S$_4$/WS$_2$-40%wt composite and d.) (left) Corresponding EDX spectrum and (right) EDX mapping images of the ZnIn$_2$S$_4$/WS$_2$-40%wt composite.

The electrochemical impedance spectroscopy (EIS) Nyquist plot of the ZnIn$_2$S$_4$/WS$_2$ heterostructures were studied in comparison to pure ZnIn$_2$S$_4$ in order to investigate the charge
transfer resistance and the separation efficiency of photo-generated electron-hole pairs. Generally, a diameter of an EIS Nyquist plot is directly proportional to the resistance to the flow of electrons at an interface of an electrode. Thus, larger the Nyquist diameter, higher the charge transfer resistance. As presented in Fig. 6a, the Nyquist diameter of all ZnIn$_2$S$_4$/WS$_2$ electrodes are smaller than that of the ZnIn$_2$S$_4$ electrode. The ZnIn$_2$S$_4$/WS$_2$-40%wt electrode provides the smallest Nyquist diameter, indicating the lowest charge transfer resistance. In addition, a larger diameter of the Nyquist plot for the physical mixture of ZnIn$_2$S$_4$ and WS$_2$, implies a higher charge transfer resistance in comparison to the ZnIn$_2$S$_4$/WS$_2$-40%wt composite, suggesting a poor charge separation efficiency due to the physical interaction between the individual materials.

The photoluminescence (PL) emission spectra of the composites were also studied to investigate the recombination rate of photo-generated electrons and holes. Typically, in a PL experiment, electrons from valence band are excited to conduction band (or sub-bands) at certain excitation wavelength. These electrons may return to the valence band arising a PL signal. The higher PL emission intensity, the higher in the probability of the photo-generated charge carriers being recombined, thus resulting in a lower photocatalytic performance. As shown in Fig. 6b, the PL emission peaks of all samples are centered at 670 nm, and the emission intensities of all ZnIn$_2$S$_4$/WS$_2$ composites are lower than that of ZnIn$_2$S$_4$. These finding clearly indicate that the formation of the ZnIn$_2$S$_4$/WS$_2$ heterostructure with intimate and efficient interfacial contact is beneficial to promote photo-generated charge transfer across the heterojunction boundary as well as suppress the photo-generated electron-hole pair recombination, which are consistent with the result from the EIS measurement. Consistently, the ZnIn$_2$S$_4$/WS$_2$-40%wt composite shows the weakest PL emission intensity and smallest diameter on EIS Nyquist plot, indicating the most efficient suppression of the charge
recombination as well as the great separation of photo-generated charge carriers and interfacial charge transportation under visible light irradiation.

![Graph](image)

**Fig.6.** a.) EIS Nyquist plots and b.) PL emission spectra of the ZnIn$_2$S$_4$/WS$_2$ composites in comparison with ZnIn$_2$S$_4$.

The band positions of the ZnIn$_2$S$_4$ and WS$_2$ photocatalysts were calculated by the following equations; $E_{VB} = E_{CB} + E_g$ and $E_{CB} = X - E_e - 0.5E_g$, derived via the Mulliken electronegativity theory, where $E_{VB}$ is the valence band potential, $E_{CB}$ is the conduction band potential, $X$ is the absolute electronegativity of the semiconductor materials (4.82 eV for ZnIn$_2$S$_4$ and 5.33 eV for WS$_2$), $E_e$ is the free electrons estimated energy on the hydrogen scale (4.50 eV), and $E_g$ is the ZnIn$_2$S$_4$ and WS$_2$ band gap energies. According to the $E_g$ values (2.81 eV for ZnIn$_2$S$_4$ and 1.83 eV for WS$_2$) calculated from the UV-visible DRS analysis (Fig. 3a), the $V_B$ and $C_B$ of ZnIn$_2$S$_4$ are 1.70 eV and -1.11 eV, respectively, and the $V_B$ and $C_B$ of WS$_2$ are 1.74 eV and -0.09 eV, respectively.

To confirm the $E_{VB}$ and $E_{CB}$ of ZnIn$_2$S$_4$ and WS$_2$, Mott-Schottky measurement was carried out. As presented in Fig. 7, the slope of the Mott-Schottky plots of ZnIn$_2$S$_4$ and WS$_2$ electrodes are positive, indicating an n-type characteristic of both ZnIn$_2$S$_4$ and WS$_2$. In addition, by extrapolating the Mott-Schottky curves to the $1/C^2 = 0$, the flat band potentials
(E_F) of ZnIn_2S_4 and WS_2 are -1.22 V and -0.20 V (vs. Ag/AgCl), respectively, which correspond to -1.01 V and 0.01 V (vs. NHE), respectively. Typically, E_CB of an n-type semiconductor is ~0.1 V more negative than its flat band potential. Therefore, the C_B of ZnIn_2S_4 and WS_2 is -1.11 eV and -0.09 eV, respectively. Combining with the above E_g values, the E_VB of ZnIn_2S_4 and WS_2 are 1.70 eV and 1.74 eV, respectively. As summarized in Table 2, the E_VB and E_CB of ZnIn_2S_4 and WS_2 are in accordance with the Mulliken electronegativity data.

3.3. Photocatalytic activity of the ZnIn_2S_4/WS_2 composite for H_2 production

The photocatalytic H_2 production activities of the ZnIn_2S_4/WS_2 photocatalyst samples, evaluated under UV-visible irradiation, in comparison with the ZnIn_2S_4 and WS_2 photocatalysts are shown in Fig. 8a. Under the same experimental conditions, all ZnIn_2S_4/WS_2 photocatalysts
exhibit higher photocatalytic H2 production rate than those of either ZnIn2S4 (145.3 μmol h⁻¹ g⁻¹) and WS2 (44.0 μmol h⁻¹ g⁻¹) photocatalysts. With increased the WS2 loading, the photocatalytic H2 production activity increases and reaches a maximum at 293.3 μmol h⁻¹ g⁻¹ when 40%wt of WS2 is introduced. The improvement of the H2 production rate is two-times higher than that of the ZnIn2S4 photocatalyst. In addition, the apparent quantum yield (AQY) of the ZnIn2S4/WS2-40%wt photocatalyst reaches 9.22%, which is much higher than that of pure ZnIn2S4 (3.73%). Moreover, the calculated AQY for the ZnIn2S4/WS2-40%wt photocatalyst exhibits much higher quantum yield for H2 production than the previously reported literatures related to ZnIn2S4-based composite photocatalysts as summarized in Table S1 (see Supporting Information). These results demonstrate that WS2 is an effective co-catalyst for improving the photocatalytic efficiency of the ZnIn2S4 photocatalyst. When the WS2 content is above 40%wt, the photocatalytic activity is found gradually decrease. This may because the excess WS2 on the surface of ZnIn2S4 not only shields the active site of the ZnIn2S4 photocatalyst but also blocks the incident light absorption of the composite photocatalyst.

From this result, finding the optimum ratios of ZnIn2S4 and WS2 in the composite would promote a great separation of photo-generated charge carriers, resulting in an improvement in the photocatalytic activity. The H2 production activity of the physical mixture of ZnIn2S4 and 40%wt of WS2 was also investigated for comparison. As presented in Figure 8a, the ZnIn2S4/WS2-40%wt heterojunction photocatalyst exhibits obviously higher H2 production rate (293.3 μmol h⁻¹ g⁻¹) than those of pure ZnIn2S4 (145.3 μmol h⁻¹ g⁻¹) and physical mixture of ZnIn2S4 and WS2 (101.3 μmol h⁻¹ g⁻¹), indicating that the enhanced photocatalytic activity of the composite is originated by the efficient charges separation and transportation at the chemically contact interface between ZnIn2S4 and WS2, corresponding to the EIS and PL studies.
On a basis of the characterization results, a “type-II band alignment” of the ZnIn$_2$S$_4$/WS$_2$ heterojunction and a photo-generated charge transfer process are proposed in Fig. 8b. Under UV-visible light irradiation, the ZnIn$_2$S$_4$/WS$_2$ photocatalyst is simultaneously excited, generating electron-hole pairs. The photo-generated electrons transfer from the C$_B$ of ZnIn$_2$S$_4$ to the C$_B$ of WS$_2$ due to the more positive C$_B$ potential of WS$_2$ (-0.09 eV) compared to that of ZnIn$_2$S$_4$ (-1.11 eV). The photo-generated holes can migrate the opposite way through the heterojunction. Then, the accumulated electrons in the C$_B$ of WS$_2$ reduce H$^+$ ions to produce H$_2$ gas since the C$_B$ of WS$_2$ is more negative than the hydrogen reduction potential (H$^+$/H$_2$ = 0.00 V vs. NHE). Moreover, the H$^+$ ions in the solution can strongly bond to the sulfur atoms on exposed WS$_2$ edges, which is easily reduced to H$_2$ gas by electrons. At the same time, photo-generated holes react with the sacrificial reagents (S$^{2-}$ and SO$_3^{2-}$) for oxidation processes.

To evaluate recyclability of the ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalyst for the photocatalytic H$_2$ production, three sequential tests were carried out. As illustrated in Fig. 8c, the H$_2$ production rate slightly decreases by about 5.7% after three-cycle tests, suggesting that the photocatalyst substantially retains its photocatalytic activity for H$_2$ production. Furthermore, the photocatalytic H$_2$ production activities of the ZnIn$_2$S$_4$/WS$_2$ composite photocatalyst under UV-visible irradiation ($\lambda > 385$ nm) and visible light irradiation ($\lambda > 400$ nm) were also investigated in comparison to the ZnIn$_2$S$_4$ as shown in Fig. 8d. As expected, either ZnIn$_2$S$_4$ or ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalysts appear to be more active in UV-visible region than visible region. In this work, under the UV-visible and visible regions, the H$_2$ production rate over the ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalyst is twice as high in comparison to the pure ZnIn$_2$S$_4$. This confirms that the ZnIn$_2$S$_4$/WS$_2$ composite actives in both UV and visible regions.
Fig. 8. a.) \( \text{H}_2 \) production rate of the \( \text{ZnIn}_2\text{S}_4 \), \( \text{WS}_2 \) and \( \text{ZnIn}_2\text{S}_4/\text{WS}_2 \) photocatalysts under UV-visible light irradiation, b.) a “type-II band alignment” and a photo-generated charge transfer in the \( \text{ZnIn}_2\text{S}_4/\text{WS}_2 \) heterojunction, c.) recyclability of the \( \text{ZnIn}_2\text{S}_4/\text{WS}_2-40\% \text{wt} \) photocatalyst under UV-visible light irradiation during 3 h, and d.) \( \text{H}_2 \) production rate of the \( \text{ZnIn}_2\text{S}_4/\text{WS}_2-40\% \text{wt} \) photocatalyst under UV-visible and visible regions using 385 nm and 400 nm filter cut-off, respectively, in comparison with the \( \text{ZnIn}_2\text{S}_4 \) photocatalyst.

3.4. Photocatalytic activity of the \( \text{ZnIn}_2\text{S}_4/\text{WS}_2 \) composite for Cr(VI) reduction

The photocatalytic Cr(VI) reduction activities of the \( \text{ZnIn}_2\text{S}_4 \), \( \text{WS}_2 \) and \( \text{ZnIn}_2\text{S}_4/\text{WS}_2-40\% \text{wt} \) are illustrated in Fig. 9a. The blank experiment without the \( \text{ZnIn}_2\text{S}_4 \), \( \text{WS}_2 \) and \( \text{ZnIn}_2\text{S}_4/\text{WS}_2-40\% \text{wt} \) photocatalysts shows no apparent photocatalytic activity, suggesting that Cr(VI) is highly stable during photolytic reaction. After stirring in the dark condition for 30 min, pure \( \text{ZnIn}_2\text{S}_4 \) shows higher adsorption capacity than \( \text{ZnIn}_2\text{S}_4/\text{WS}_2-40\% \text{wt} \) and pure \( \text{WS}_2 \),
respectively, corresponding to the BET surface area analysis (46, 39 and 15 m²/g for pure ZnIn₂S₄, ZnIn₂S₄/WS₂-40%wt and pure WS₂, respectively). The ZnIn₂S₄/WS₂-40%wt composite exhibits higher photoreduction efficiency than those single materials under the same irradiation times. The photoreduction efficiency of the ZnIn₂S₄/WS₂-40%wt, ZnIn₂S₄ and WS₂ are 93.6%, 78.4% and 4.2%, respectively, after 120 min of the light irradiation. The reaction kinetics is consistent with a pseudo-first-order model, which is suitable for a low concentration of solution, and obtained by the following equation: \( \ln(C_0 - C) = kt \), where \( k \) is the Cr(VI) reduction rate constant and \( t \) is the irradiation time. As shown in Fig. 9b, the determined rate constant \( (k) \) of the ZnIn₂S₄/WS₂-40%wt, ZnIn₂S₄ and WS₂ are \( 2.1 \times 10^{-2} \), \( 1.0 \times 10^{-2} \) and \( 0.02 \times 10^{-3} \) \( \text{min}^{-1} \), respectively, with good linear correlation coefficients \( (R^2 > 0.97) \). The rate constant for the Cr(VI) reduction of the ZnIn₂S₄/WS₂-40%wt exhibits two times higher than that of the ZnIn₂S₄, corresponding with the photocatalytic H₂ production results. Even though the BET surface area of the ZnIn₂S₄/WS₂-40%wt composite slightly decreases when compared to pure ZnIn₂S₄, the composite exhibits the highest photocatalytic efficiency. This demonstrates that, in this case, surface area does not significantly affect the photocatalytic activity of the ZnIn₂S₄/WS₂ photocatalyst.

In addition, the Cr(VI) photoreduction of the physical mixture of ZnIn₂S₄ and WS₂ was tested. As shown in Fig. 9a and 9b, the ZnIn₂S₄/WS₂-40%wt composite photocatalyst exhibits enhanced efficiency in comparison to the physical mixture (44.4% with the \( k \) value of \( 0.4 \times 10^{-2} \) \( \text{min}^{-1} \)). In addition, the apparent quantum yield (AQY) of the ZnIn₂S₄/WS₂-40%wt composite was calculated to be 5.89% which is about 1.2 times higher than that of ZnIn₂S₄ (4.72%) and was close to the previously reported literature related to ZnIn₂S₄-based composite photocatalyst as presented in Table S2 (see Supporting Information). These results illustrated that the combination between ZnIn₂S₄ and WS₂ is a promising approach to improve the photocatalytic activity of ZnIn₂S₄.
The effect of pH value of the Cr(VI) solution on the photoreduction efficiency of the ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalyst was also investigated by varying the pH value in range of 4 to 8 with the constant photocatalyst dosage and initial Cr(VI) concentration (Fig. 9c). When the pH value is decreased from 6 (initial pH) to 4, the photoreduction activity is increased from 93.6 to 98.5% with the $k$ value of 3.3x10$^{-2}$ min$^{-1}$ (Fig. 9d). However, in the basic solution (pH = 8), the photoreduction efficiency is decreased to 9.3% with the $k$ value of 1.1x10$^{-3}$ min$^{-1}$. This is probably because, during the Cr(VI) reduction, Cr(OH)$_3$ produced from CrO$_4^{2-}$ ion (Equation (6)) coats on the active surface of the photocatalyst, lowering the Cr(VI) reduction activity.\(^{59}\)

In addition, CrO$_4^{2-}$ in the basic solution is not easier to be reduced than Cr$_2$O$_7^{2-}$ and HCrO$_4^-$ in acidic solution due to a lower reduction potential of CrO$_4^{2-}$/Cr$^{3+}$ (-0.13 V vs. NHE) than that of Cr$_2$O$_7^{2-}$/Cr$^{3+}$ (1.23 V vs. NHE) and HCrO$_4^-$/Cr$^{3+}$ (1.35 V vs. NHE).\(^4\) Furthermore, according to the Le Chatelier's principle\(^61\), the increase in the concentration of hydroxide (OH$^-$) ions or decrease in the concentration of protons (H$^+$) results in a slower reach of the chemical equilibrium (Equation (6)), suggesting that Cr(VI) ion is effectively reduced to Cr(III) ion in the acidic solution rather than the basic solution.

UV-vis absorption spectral change of the Cr(VI) solution during the photoreduction reaction in the presence of the ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalyst at pH = 4 (Fig. 9e) illustrate that the absorption peak intensity of Cr(VI) at 532 nm gradually decrease with increasing irradiation time and the Cr(VI) photoreduction is almost completed when the irradiation is continued up to 120 min. To confirm an occurrence of Cr(III) ions after photocatalysis, the NaOH solution was added into the Cr(VI) solutions before and after 120 min of light irradiation. A pale gray precipitate of Cr(OH)$_3$ immediately took place for the solution after the light irradiation.\(^62\) These results evidently indicate that Cr(VI) ion has been completely reduced to Cr(III) ion.
Fig. 9. a.) Photoreduction efficiency and b.) pseudo-first-order kinetics of the Cr(VI) photoreduction at pH 6 (the initial pH of the solution). c.) Effect of pH of the solution and d.) pseudo-first-order kinetics of the Cr (VI) photoreduction. e.) (left) UV-vis absorption spectra change of the Cr(VI) solution during the photoreduction reaction in the presence of the ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalyst at pH = 4 and (right) the change that took place when
NaOH solution was added to the Cr(VI) solutions before and after visible light irradiation for 120 min.

The recyclability of the ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalyst for the photoreduction of Cr(VI) reaction was investigated by a three-run cycle test at pH of the solution of 4. The result (Fig. 10a) shows an insignificantly decreased efficiency by about 5.4% after three cycles. This result indicates that the ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalyst provides a good recyclability for the Cr(VI) photoreduction. Notably that the slightly decreased efficiencies for the Cr(VI) photoreduction and H$_2$ production are probably because the loss of the photocatalyst during the recovery process. XRD spectra and SEM images of the ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalyst after three-cycle test were analyzed to evaluate its photostability for the photocatalytic H$_2$ production and Cr(VI) photoreduction. The XRD spectra (Fig. 10b) of the fresh photocatalyst, and the used photocatalyst reveal that the diffraction reflections are little (not significant) changed after the photocatalytic recycling. In addition, the FESEM images show that the morphologies of ZnIn$_2$S$_4$ and WS$_2$ in the ZnIn$_2$S$_4$/WS$_2$-40%wt composite photocatalyst remain unchanged (Fig. 10c-10d). These results imply that the ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalyst is reusable and stable under the reaction conditions.

A possible mechanism for the photocatalytic Cr(VI) reduction process is illustrated in Fig. 10e. Since the C$_B$ of WS$_2$ (-0.09 eV) is more negative than the reduction potential of Cr(VI)/Cr(III) (1.33 V vs. NHE)$^{63}$, the photo-generated electrons can reduce the Cr(VI) ion to Cr(III) ion. Simultaneously, the H$_2$O can be oxidized to O$_2$ by the photo-generated holes since the reduction potential of O$_2$/H$_2$O (1.23 V vs. NHE) is less positive than the V$_B$ of ZnIn$_2$S$_4$ (1.70 eV).$^{64}$ The reaction steps are also provided as follows $^4$:

$$ZnIn_{2}S_4/WS_2 + h\nu (\text{visible}) \rightarrow ZnIn_{2}S_4 (e_{CB}^- + h_{VB}^+) + WS_2 (e_{CB}^- + h_{VB}^+) \quad (1)$$

$$ZnIn_{2}S_4 (e_{CB}^- + h_{VB}^+) + WS_2 (e_{CB}^- + h_{VB}^+) \rightarrow ZnIn_{2}S_4 (h_{VB}^+) + WS_2 (e_{CB}^-) \quad (2)$$
\[ 2\text{H}_2\text{O} + \text{ZnIn}_2\text{S}_4(4\text{h}_\text{VB}^+) \rightarrow \text{O}_2 + 4\text{H}^+ \]  
(3)

under acidic condition,

\[ \text{Cr}_2\text{O}_7^{2-} + 14\text{H}^+ + \text{WS}_2(6\text{e}_\text{CB}^-) \rightarrow 2\text{Cr}^{3+} + 7\text{H}_2\text{O} \]  
(4)

\[ \text{HCrO}_4^- + 7\text{H}^+ + \text{WS}_2(3\text{e}_\text{CB}^-) \rightarrow \text{Cr}^{3+} + 4\text{H}_2\text{O} \]  
(5)

under basic condition,

\[ \text{CrO}_4^{2-} + 4\text{H}_2\text{O} + \text{WS}_2(3\text{e}_\text{CB}^-) \rightarrow \text{Cr(OH)}_3 + 5\text{OH}^- \]  
(6)

Based on the photocatalytic experimental results, WS\textsubscript{2} acts as an efficient co-catalyst in the ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} system. More importantly, the intimate interface between ZnIn\textsubscript{2}S\textsubscript{4} and WS\textsubscript{2} facilitates the photo-generated charge carriers transfer between ZnIn\textsubscript{2}S\textsubscript{4} and WS\textsubscript{2} through heterojunction between the surface interaction, which is a vital factor for improving the photocatalytic activity of the ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} composite for the Cr(VI) reduction and H\textsubscript{2} production.
**Fig. 10.** a.) Recyclability of the ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalyst performed at pH 4. b.) XRD patterns and c.)-d.) FESEM images of the used ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalysts after three-cycle test. e.) a proposed mechanism of the Cr(VI) photoreduction by the ZnIn$_2$S$_4$/WS$_2$-40%wt photocatalyst under visible light irradiation.

**Conclusions**

ZnIn$_2$S$_4$/WS$_2$ composites with well-defined flower-like ZnIn$_2$S$_4$ microspheres were successfully synthesized by microwave synthesis method using L-cysteine as the sulfur source.
and applied for photocatalytic H\textsubscript{2} production and Cr(VI) photoreduction. The loading amount of WS\textsubscript{2} played an important role on the photocatalytic H\textsubscript{2} production activity under UV-visible light irradiation. The ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2}-40\%wt photocatalyst exhibited the highest H\textsubscript{2} production rate. In addition, this composite photocatalyst also exhibited excellent photocatalytic Cr(VI) reduction activity under visible light irradiation where the photoreduction efficiency of the composite photocatalyst was better for the acidic solutions (pH 4 and 6) than that for the basic solution (pH 8). Moreover, the ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} photocatalyst show excellent recyclability with minimal loss of the photoactivity on use and good stability during the photocatalytic processes. The enhanced photocatalytic performance of the ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} photocatalyst was ascribed to the efficient separation and transportation of the photo-generated electron–hole pairs through the “type II heterojunction” at the interface in the ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} composite as well as the increase in the visible-light response. The results of this work demonstrated that the synthesized ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} composite is a promising photocatalyst for the applications in photocatalytic H\textsubscript{2} production and heavy metal ion pollutants elimination. Besides that, the microwave synthesis method is the potentially useful method for preparing of either the single-component ZnIn\textsubscript{2}S\textsubscript{4} or the ZnIn\textsubscript{2}S\textsubscript{4}/WS\textsubscript{2} composite material as well as other composite materials.
