#### 24 Abstract

Several studies have suggested that the Earth's upper mantle is slightly enriched in light 25 molybdenum isotopes relative to bulk Earth, defined by chondrites, but there is no consensus on the 26 presence of this subtle but potentially notable signature. To establish better whether or not the 27 28 <sup>98</sup>Mo/<sup>95</sup>Mo of Earth's upper mantle is indeed sub-chondritic, we have analysed hand-picked glasses of 29 depleted (i.e. chondrite normalised La/Sm<1) mid-ocean ridge basalts (MORB) from the Pacific, Atlantic and Indian ocean basins. The mean Mo isotope composition of our depleted MORB relative to 30 31 reference NIST SRM 3134 ( $\delta^{98/95}$ Mo<sub>NIST SRM 3134</sub>) is -0.22±0.03‰ (95% confidence interval, c.i.) compared to a value of -0.15±0.01‰ (95% c.i.) for bulk Earth. Our high precision analyses of the 32 <sup>234</sup>U/<sup>238</sup>U activity ratios of these samples are within uncertainty of unity, which rules out the effect of 33 possible secondary, sea-floor processes as the dominant cause of their low  $\delta^{98/95}$ Mo<sub>NIST SRM 3134</sub>. We 34 further report experimental data showing that sulphide liquid has  $\delta^{98/95}$ Mo<sub>NIST SRM 3134</sub> 0.25±0.01‰ lower 35 36 than basaltic silicate liquid at 1400°C. This fractionation is too small to significantly alter the Mo 37 isotope composition of basalts relative to their sources during melting or differentiation.

Our MORB data show that resolvably sub-chondritic Mo isotope compositions are common in the 38 upper mantle. Moreover, an appropriately weighted average  $\delta^{98/95}$ Mo<sub>NIST SRM 3134</sub> of depleted and 39 enriched MORB, taken from this study and the literature, yields an estimated mantle value of 40 -0.20±0.01‰, indicating that the upper mantle as a whole is sub-chondritic. Since prior work 41 demonstrates that core formation will not create a residual silicate reservoir with a sub-chondritic 42 43  $\delta^{98/95}$ Mo<sub>NIST SRM 3134</sub>, we propose that this feature is a result of recycling oceanic crust with low  $\delta^{98/95}$ Mo<sub>NIST SRM 3134</sub> because of Mo isotope fractionation during subduction dehydration. Such an origin 44 is in keeping with the sub-chondritic Th/U and low Ce/Pb of the depleted mantle, features which cannot 45 be explained by simple melt extraction. We present mass balance models of the plate tectonic cycle that 46 quantitatively illustrate that the  $\delta^{98/95}$ Mo<sub>NIST SRM 3134</sub> of the Earth's mantle can be suitably lowered by 47 48 such oceanic crustal recycling. Our Mo isotope study adds to the notion that the depleted mantle has been substantially modified by geodynamic cycling of subduction-processed oceanic crust. 49

#### 51 **1 Introduction**

52 Traditionally, trace element abundances and radiogenic isotopes have been used to investigate the 53 recycling of elements from crust to mantle and its consequences for the chemical evolution of the 54 terrestrial mantle. Mass-dependent variations in isotope ratios have also attracted attention as proxies for this process, as relatively large isotopic fractionations at low temperatures near the Earth's surface 55 56 should diagnostically fingerprint recycled material (e.g. Andersen et al., 2015). Molybdenum isotope measurements of mantle derived samples offer some promise in this context. Notably, fractionation 57 58 during dehydration of the subducting slab appears to generate a fluid with isotopically heavy Mo, as 59 inferred from the compositions of mafic arc lavas (Freymuth et al., 2015; König et al., 2016; Villalobos-60 Orchard et al., 2020), and a complementary, isotopically light residue, manifest in exhumed eclogites (Chen et al., 2019). Stirring subduction-processed material back into the mantle should therefore impart 61 an isotopically light Mo signature (Chen et al., 2019; Freymuth et al., 2015), although a similar effect 62 63 has been proposed to result from melt depletion (McCoy-West et al., 2019).

An attractive aspect of the Mo isotope system is that as a refractory and siderophile element, 64 analyses of chondrites and (magmatic) iron meteorites should provide a reliable estimate for the bulk 65 Earth, and a reference against which the effects of recycling can be gauged. Two studies of such 66 meteorites yield consistent  $\delta^{98/95}$ Mo<sub>NIST SRM 3134</sub> (i.e. <sup>98</sup>Mo/<sup>95</sup>Mo relative to international reference 67 standard NIST SRM 3134; hereafter  $\delta^{98/95}$ Mo), with values of  $-0.16\pm0.02\%$  (Burkhardt et al., 2014) 68 and -0.14±0.01‰ (Liang et al., 2017), yielding an overall mean of -0.15±0.01‰. For simplicity, we 69 henceforth refer to this value as 'chondritic'. Although Mo is siderophile, and so the Mo abundance of 70 71 the silicate Earth is strongly influenced by core formation, experimental studies imply that metal 72 segregation either does not fractionate the Mo isotope composition of the residual silicate mantle or 73 slightly enriches it in heavy Mo isotopes (Hin et al., 2019, 2013). Thus, recent studies of (ultra-)mafic 74 rocks suggesting that the Mo isotope composition of the Earth's mantle is isotopically light relative to 75 chondrites (Bezard et al., 2016; Liang et al., 2017; McCoy-West et al., 2019), seemingly identify a 76 significant geochemical perturbation of the mantle since core-mantle separation.

Agreement on the  $\delta^{98/95}$ Mo of Earth's mantle, however, has not yet emerged. There appears a tendency of depleted MORB (i.e. with sub-chondritic La/Sm or (La/Sm)<sub>N</sub><1) to have sub-chondritic

 $\delta^{98/95}$ Mo and enriched MORB (i.e. (La/Sm)<sub>N</sub>>1) to have slightly super-chondritic  $\delta^{98/95}$ Mo (Bezard et 79 80 al., 2016; Chen et al., 2022). Yet, the study by Bezard et al. (2016) also documents two depleted MORB with positive  $\delta^{98/95}$  Mo, while Liang et al. (2017) obtained super-chondritic values for all their depleted 81 82 and enriched MORB. Given this uncertainty in the composition of the modern mantle, it is unsurprising that there are also different perspectives on the evolution of  $\delta^{98/95}$ Mo through mantle history. A dataset 83 of bulk komatiite analyses, with highly variable  $\delta^{98/95}$ Mo, has been filtered for the effects of alteration 84 and used to argue for sub-chondritic mantle  $\delta^{98/95}$ Mo as early as the Archaean (McCoy-West et al., 85 86 2019). Yet, previously, some of these same analyses were used to argue for a chondritic Archaean 87 mantle (Greber et al., 2015).

Our main aim here is to try to evaluate better the  $\delta^{98/95}$ Mo of the modern, upper mantle. To this end, we analyse a new set of samples focussed on depleted MORB. To aid in interpretation, we also present results from sulphide-silicate experiments to investigate the importance of fractionation between these two phases in accounting for observed Mo isotope variability, as Mo isotope fractionation might occur during removal of sulphide on both a local (sulphur fractionation during MORB genesis; Mathez, 1976) and global scale (O'Neill, 1991).

94

### 95 2 Samples

All MORB analyses are made on fresh, hand-picked glasses from previously well-characterised 96 samples. We analysed samples from active spreading centres in the three major ocean basins. Five 97 samples are from the East Pacific Rise between 9°30'-11°30' N (Niu et al., 1999; Regelous et al., 1999; 98 Sims et al., 2002), a fast-spreading ridge with a full spreading rate of 110 mm yr<sup>-1</sup>. A single Atlantic 99 sample originates from the southern Mid-Atlantic Ridge at ~26° S (Batiza et al., 1988; Niu and Batiza, 100 1994), where the full spreading rate is about 35-40 mm yr<sup>-1</sup>. We analysed four samples from the 101 Southwest Indian Ridge (SWIR) at 57° E and 66° E (Robinson et al., 1996), which are slow-spreading 102 segments with a full spreading rate of 13-16 mm yr<sup>-1</sup>. Samples are from neo-volcanic zones with 103 104 eruption ages <100 ka. None of these sites show any influence of hotspot activity.

105 We focussed on depleted MORB to be representative of the depleted, upper mantle complementary
106 to continental crust. All samples have chondrite normalised La/Sm<1 (Table 1), except one E-MORB</li>

from the Pacific (PH108-1) and two Atlantic E-MORB that represent re-analyses of samples presented
in Liang et al. (2017). The radiogenic isotope compositions of our MORB samples are shown in Figure
1, illustrating their generally depleted character (our Pacific and Atlantic MORB have <sup>143</sup>Nd/<sup>144</sup>Nd
>0.5131) and the distinctive 'DUPAL' signature of SWIR samples, with relatively unradiogenic Pb and
Nd and radiogenic Sr.

112

### 113 **3 Methods**

### 114 *3.1 Sample preparation*

Using a binocular microscope, we hand-picked up to 1.5 g of optically clear glass, without 115 phenocrysts or other inclusions, and carefully avoided visible signs of alteration. Some samples 116 analysed for Mo in this work had already been processed in the U isotope study of Andersen et al. 117 (2015). For these samples, picked glass chips were leached thrice by shaking them for 15 minutes each 118 time in a mixture of 0.05M hydroxylamine hydrochloride, 15% acetic acid and 0.03M EDTA at a pH 119 of 4. This reductive leaching technique (Gutjahr et al., 2007) dissolves Fe-Mn precipitates, such as those 120 121 that accumulate on sea-floor basalts. These Fe-Mn coatings are potentially problematic, as their strong sorption of elements such as U and Mo from seawater produces a contaminant with contrasting isotopic 122 123 composition to mantle derived basalts. Consequently, reductive leaching has been widely used in U-124 series analyses of MORB and this represents an appropriate precautionary step for Mo isotope analysis. For example, inadvertent inclusion of a  $10^{-4}$  mass fraction of Fe-Mn coating with a highly fractionated 125  $\delta^{98/95}$ Mo of up to -2‰ in a typical MORB glass analysis would decrease its  $\delta^{98/95}$ Mo by ~0.07‰. 126

The leachates were analysed for their elemental contents using an inductively-coupled plasma mass 127 spectrometer (ICP-MS; Thermo Scientific Element 2) at the University of Bristol. As discussed in 128 129 Andersen et al. (2015), leaching appears to result in minor glass dissolution and so some Mo is removed in the process (see Table S1 in the online Supplementary Materials). Dissolution was most significant 130 in the sample picked from the finest glass fragment size (D14-1). However, there was no systematic, 131 preferential removal during leaching of Mo relative to elements not adsorbed onto Fe-Mn coatings. We 132 therefore inferred our samples were sufficiently young and our picking procedure was sufficiently 133 rigorous that the leaching step was unnecessary, and some of the samples analysed later in the study 134

135 were not leached (2370-6, PH108-1, ALV 518-3-2, 45N). Moreover, most samples were analysed for their  ${}^{234}U/{}^{238}U$  activity ratios, expressed as  $({}^{234}U/{}^{238}U)$ . These activity ratios provide an important check 136 on possible influences of Fe-Mn coatings, which would perturb this ratio from a secular equilibrium 137 value of unity. To check that leaching did not cause any Mo isotope fractionation by preferential 138 139 dissolution, we analysed a glassed sample of USGS reference material BHVO-2 that then underwent the same leaching procedure (see Andersen et al., 2015 and Table S1). The Mo isotope composition of 140 leached BHVO-2 glass, just like the original powder (Table 1), falls within the reproducibility of 141 142 BHVO-2 found in the literature (Table S2).

143

#### 144 *3.2 Analytical techniques*

Samples were dissolved in mixtures of high purity 28M HF, 15M HNO3 and 6M HClO4 after 145 addition of a <sup>97</sup>Mo-<sup>100</sup>Mo double spike and in most cases also a <sup>233</sup>U-<sup>236</sup>U double spike, for high precision 146 <sup>238</sup>U/<sup>235</sup>U analysis. Both Mo and U isotope analyses were performed on a Thermo Finnigan Neptune 147 multi-collector ICP-MS (s/n 1020) at the University of Bristol. Pacific samples 2370-6, PH108-1 and a 148 repeat digestion of sample 2504-1 were only spiked with <sup>97</sup>Mo-<sup>100</sup>Mo and analysed for their Mo isotope 149 composition. After digestion and drying, all samples were refluxed twice in 6M HCl to break down 150 151 fluorides prior to dissolution for ion exchange chromatography. Samples containing a U double spike were first passed through U chemistry protocols. Matrix eluted during U purification was collected, 152 dried and refluxed in 6M HCl for Mo chemistry protocols. 153

All procedures are described in detail for U in Andersen et al. (2015) and for Mo in Willbold et al. 154 (2016), Hin et al. (2019) and Chen et al. (2019), and we refer the reader to the online Supplementary 155 Material for a brief summary. An important detail is that we monitor both masses 99 and 101 during all 156 157 measurements and only accept data where Ru interference corrections using both masses yield results 158 within uncertainty of each other (see Supplementary Material). Occasionally, interferences occur on these masses that are evidently not Ru and can influence results without this precaution. Such effects 159 might account for some of the inconsistencies in the current literature, as typically only mass 99 is 160 161 monitored.

During the course of this study we have analysed  $\delta^{98/95}$ Mo in a variety of geological reference 162 materials with Mo contents between  $\sim 30 \text{ ng g}^{-1}$  and  $\sim 4 \mu \text{g} \text{ g}^{-1}$  and obtained good agreement with 163 literature data (see Table S2). We note that geological reference material W-2a provides a useful test of 164 chemical procedures at low Mo concentrations appropriate for MORB analyses, without the more 165 166 severe challenge posed by the extremely Mo depleted BIR-1. Based on W-2a analyses in Bristol, presented here and in Chen et al. (2019), the reproducibility of our Mo analyses is  $\pm 0.04\%$  (2 standard 167 deviations, 2s) as derived from 30 measurements of 16 W-2a digestions; in this study, each of these 30 168 169 measurements typically consisted of 3 repeated analyses.

As the number of analyses performed on basalts in this study is  $\leq 3$ , all uncertainties we present on  $\delta^{98/95}$ Mo of these individual samples are 2s, based on the long-term reproducibility of W-2a (Table 1). Instead,  $\delta^{98/95}$ Mo of experimental samples and calculated population means for ocean basins and bulk mantle are presented with 95% confidence intervals (95% c.i.), calculated based on the reproducibility of W-2a for individual samples or based on within-group variance for population means as  $t_{0.95} \times s/\sqrt{n}$ where  $t_{0.95}$  is a two-way Student's *t*-factor.

Run products of experiments (see below) were analysed by electron microprobe to determine their major and minor element compositions. These analyses were performed on a Jeol JXA8600 at the Department of Archaeology at the University of Oxford, according to the protocols described in Kiseeva and Wood (2013). Both phases were analysed with a 10 µm diameter beam of 20 nA at an accelerating voltage of 15 kV. Values in Table 2 represent means of at least 25 spots, with uncertainties based on the variance of those spots.

182

# 183 *3.3 Isotope Fractionation Experiments*

We determined experimentally the Mo isotope fractionation between liquid sulphide and liquid silicate to enable accurate predictions of the effects of sulphide extraction during MORB formation and differentiation. Two experiments were performed following the procedures of Kiseeva and Wood (2013). The experimental charges consisted of a 1:1 mixture (by mass) of silicate and FeS powders (see Table 2 for its composition). The silicate powder consisted of a mixture of CaO, MgO, Al<sub>2</sub>O<sub>3</sub> and SiO<sub>2</sub>

in proportions akin to the anorthite-diopside-forsterite eutectic at 1.5 GPa (An<sub>50</sub>Di<sub>28</sub>Fo<sub>22</sub>), which is a 189 simplified haplobasalt. This powder was prepared from analytical grade oxides and CaCO<sub>3</sub> that were 190 191 ground and mixed prior to gradual heating from 500°C to 950°C in air and subsequent decarbonation at 950°C for two hours. An additional 10 wt% FeO and 2 wt% MoO<sub>2</sub> powder was then admixed. 192 Samples were loaded into graphite capsules which maintain the oxygen fugacity at or below the C-CO<sub>2</sub>-193 CO equilibrium (1-2 log units below the fayalite-magnetite-quartz buffer). The two experiments were 194 performed in an end-loaded, Boyd-and-England-type piston cylinder apparatus at the University of 195 196 Oxford at a pressure of 1.5 GPa and a temperature of 1400°C. As Hin et al. (2013) found that Mo 197 isotopes attained equilibrium within 1.5 h between liquid metal and liquid silicate at the same temperature, we ran our two experiments for two and three hours before quenching by cutting the power. 198 More experimental details can be found in Kiseeva and Wood (2013). 199

200

### 201 4 Results

Molybdenum concentrations of our Pacific and Atlantic depleted MORB vary between 0.16 and 0.40  $\mu$ g g<sup>-1</sup> (Table 1), while our Indian Ocean depleted MORB have markedly higher Mo contents (0.39-0.60  $\mu$ g g<sup>-1</sup>) in keeping with the lower degrees of melting at this slow spreading ridge (Robinson et al., 2001). Our Pacific enriched MORB sample (PH108-1) has the highest Mo content of 0.99  $\mu$ g g<sup>-1</sup>. Our samples have Ce/Mo between 26 and 55, comparable to MORB reported in other studies that presented isotope dilution measurements of Mo concentrations (Bezard et al., 2016; Liang et al., 2017; Chen et al. 2022).

209 The Mo isotope compositions of our depleted MORB samples vary between  $-0.16\pm0.04\%$  and -0.27±0.04‰ (Table 1, Figure 2). None of these values are super-chondritic, and 5 of 9 lie outside 210 uncertainties below the chondritic reference. Likewise, mean  $\delta^{98/95}$ Mo for depleted MORB from 211 212 different ocean basins have resolved, sub-chondritic values with  $-0.22\pm0.04\%$  and  $-0.19\pm0.03\%$  (95%) c.i.) for four Pacific and four Indian Ocean samples, respectively. The  $\delta^{98/95}$ Mo of MORB from Pacific 213 and Indian basins are not statistically distinguishable as different populations ( $p_{t-test}$  0.40). A single, 214 depleted Atlantic MORB yields -0.27±0.04‰. Overall, we obtain a mean Mo isotope composition of 215 216  $-0.22\pm0.03\%$  (95% c.i.) for our global suite of depleted MORB, i.e. (La/Sm)<sub>N</sub><1, which is significantly

below the mean chondritic value of  $-0.15\pm0.01\%$  (95% c.i.) (Burkhardt et al., 2014; Liang et al., 2017).

218 Our analyses of two enriched Atlantic samples, previously analysed by Liang et al. (2017), yielded 219  $\delta^{98/95}$ Mo of  $-0.04\pm0.04\%$  and  $-0.06\pm0.04\%$ , significantly higher than our depleted MORB.

220 We report some new  $(^{234}U/^{238}U)$  in Table 1, to supplement values previously reported in Andersen

et al. (2015). All measurements are within uncertainty ( $\leq 0.005$ ) of unity.

222 Both experiments equilibrating sulphide liquid with silicate liquid show reproducible  $\delta^{98/95}$ Mo in the quenched glasses as well as in the quenched FeS (Figure 3a and Table 1). We thus obtain an average 223  $\Delta^{98/95}$ Mo<sub>sulphide-silicate</sub> of -0.25±0.01‰, i.e. sulphides are 0.25‰ lighter (in terms of  ${}^{98}$ Mo/ ${}^{95}$ Mo) at 224 1400°C. We calculated a  $\delta^{98/95}$ Mo of 0.04±0.01‰ for the bulk run products, based on the mean silicate 225 226 and sulphide Mo isotope compositions, Mo concentrations and their phase proportions (determined from least squares linear regression of their major element compositions reported in Table 2). This is 227 reassuringly within uncertainty of the value  $0.02\pm0.02\%$  determined for the MoO<sub>2</sub> powder used as the 228 starting material. Furthermore, our experiments yielded a sulphide/silicate partition coefficient for Mo 229 of 23. 230

231

### 232 5 Discussion

## 233 5.1 Assessing secondary perturbation of Mo isotope ratios

234 The primary Mo isotope composition of MORB can be perturbed by direct or indirect interaction 235 with isotopically heavy seawater. Careful picking of fresh glass is the principal means to avoid the former, but it is hard to guard against possible magmatic assimilation of altered crust en route to the 236 surface or be sure there are no traces of Fe-Mn coating in picked samples. Based on measurements in 237 238 drill cores and ocean floor surveys presented in the literature, Hein et al. (2003) estimated that the ocean floor is currently covered by  $\sim 2 \times 10^{14}$  kg of Fe-Mn crust. As this is 7-8 orders of magnitude less than 239 the mass of the magmatic ocean crust, Fe-Mn crusts are irrelevant for its average Mo isotope 240 composition, but as indicated in section 3.1 they can significantly affect  $\delta^{98/95}$ Mo of individual samples. 241 Reductive leaching acts against such contamination by Fe-Mn crusts, but analysis of (<sup>234</sup>U/<sup>238</sup>U) 242 provides an important check for any style of contamination. Pristine MORB display (<sup>234</sup>U/<sup>238</sup>U) in 243 secular equilibrium, i.e. with a value of 1. Fe-Mn crusts precipitated from seawater acquire a seawater 244

(<sup>234</sup>U/<sup>238</sup>U) of about 1.14 (Koide and Goldberg, 1965), and fractionated, isotopically light Mo (Siebert
et al., 2003). Portions of mafic crust that have been altered by interaction with seawater inherit both its
elevated (<sup>234</sup>U/<sup>238</sup>U) and isotopically heavy Mo in the process (Freymuth et al., 2015). Critically, all our
samples have (<sup>234</sup>U/<sup>238</sup>U) within error of secular equilibrium. Several of our MORB samples with
(<sup>234</sup>U/<sup>238</sup>U) measured to the highest precision are clearly resolved from a mixing curve to a Fe-Mn
contaminant and cannot have acquired their sub-chondritic Mo from such perturbation (Figure 4).

251

## 252 *5.2 Mo isotope fractionation during magmatic processes*

253 It is important to consider isotopic fractionation during magma genesis when using the isotopic 254 composition of MORB to infer that of the upper mantle. McCoy-West et al. (2019) have recently explored the possibility that Mo isotopes are fractionated during mantle melting, using a model that 255 combines theoretical estimates of fractionation with partitioning and speciation data from petrological 256 experiments. Although a minor species at the current oxygen fugacity of the mantle, Mo<sup>4+</sup> is isotopically 257 lighter than the dominant Mo<sup>6+</sup> species and more strongly partitioned into mineral phases, such as 258 pyroxenes (Leitzke et al., 2017). As a net result, the Mo isotope compositions of melts become 259 260 isotopically heavier than their sources (McCoy-West et al., 2019); MORB, constituting some 10% melting, should have a  $\delta^{98/95}$ Mo ~0.02‰ higher than the upper mantle from which it is derived, at 261 modern mantle oxygen fugacity. Bezard et al. (2016) previously argued against melt-induced Mo 262 isotope fractionation, based on a lack of systematic variation of  $\delta^{98/95}$ Mo with degree of melting in their 263 sample set. However, the predicted variability in  $\delta^{98/95}$ Mo (<0.005‰) due to different degrees of melting 264 in their sample suite is likely too subtle to discern within natural and analytical scatter (e.g. Figure 2), 265 even if all MORB Mo isotope compositions should be systematically slightly heavier than their mantle 266 267 sources. Furthermore, the effects on Mo isotope ratios of the minor amounts of crystallisation experienced by MORB are likely negligible given the incompatibility of Mo in silicates typically 268 269 crystallising from MORB.

Another potential source of Mo isotope fractionation during magmatic processes is the presence of a sulphide phase (Liang et al., 2017; Voegelin et al., 2014). Chalcophile Mo partitions into sulphide that may be present in the source during melting or that may segregate from MORB during melting and differentiation, because MORB are frequently sulphide-saturated (Mathez, 1976). Experiments have
shown that the partitioning of Mo between liquid sulphide and liquid silicate is strongly dependent on
S excess relative to Fe in the sulphide, but sulphide/silicate partition coefficients of Mo during MORB
evolution are thought to be likely not much above ~20 (Lodders and Palme, 1991).

277 Figure 3b presents a Rayleigh distillation model of the effects of sulphide extraction on silicate melt  $\delta^{98/95}$ Mo, based on the fractionation factor determined in this study. These calculations imply that 278 removal of plausible amounts of immiscible sulphide liquid during melting or differentiation beneath 279 ridges does not significantly affect the  $\delta^{98/95}$ Mo of the remaining MORB, despite our observation that 280 281 silicate liquid is enriched in heavy Mo isotopes compared to coexisting sulphide liquid by 0.25±0.01‰ at 1400°C (Figure 3a, Table 1). In these models, we have used an upper limit of 23 for the Mo partition 282 coefficient based on our Ni- and Cu-free experiments. We find that ≥0.5% of the initial mass of the 283 basaltic melt must segregate as sulphide for a measurable isotopic effect of >0.04% (Figure 3b). Such 284 285 a mass fraction of sulphide is substantially larger than possible based on S abundances of  $\sim 0.2 \text{ wt}\%$ expected after melting 10% of a peridotite and a minimum S solubility in MORB of ~0.08 wt%, 286 suggesting <0.15% sulphide extraction from MORB (Mathez, 1976). As such we consider the role of 287 sulphide fractionation to have a negligible effect on the  $\delta^{98/95}$ Mo of MORB relative to its source. 288 Moreover, sulphide removal could only serve to increase the  $\delta^{98/95}$ Mo of the erupted melt relative to 289 source and cannot explain a melt with sub-chondritic  $\delta^{98/95}$ Mo derived from a chondritic mantle. 290

291

# 292 5.3 Sub-chondritic $\delta^{98/95}$ Mo of the upper mantle

Although our dataset clearly argues for sub-chondritic  $\delta^{98/95}$ Mo in depleted portions of the upper mantle, it is important to assess the  $\delta^{98/95}$ Mo of the upper mantle as a whole. Notably this requires assessing an appropriate global contribution of enriched MORB to the ridge system, as these magmas appear to have higher  $\delta^{98/95}$ Mo (Bezard et al., 2016; Chen et al., 2022). Trying to appropriately weight contributions of enriched, i.e. (La/Sm)<sub>N</sub>>1, and depleted MORB, i.e. (La/Sm)<sub>N</sub><1, we have used the compilation of Gale et al. (2013) to determine the fraction of global Mo derived from enriched and depleted ridge segments. This exercise shows that for normal ridge segments (i.e. that lie >500 km from a hotspot and are not in a back-arc setting; Gale et al., 2013), 78% of Mo is associated with depleted
MORB compositions.

We have also calculated concentration-weighted mean  $\delta^{98/95}$ Mo for depleted and enriched MORB 302 using a compilation of our own and literature data. This requires some care given inconsistencies within 303 304 published data noted in the introduction and a possible analytical cause of this highlighted in section 305 3.2. We have used data from this study, Chen et al. (2022) and Bezard et al. (2016; excluding their two anomalous, super-chondritic values of depleted MORB from further consideration, as the authors did 306 307 themselves). We do not include any data from Liang et al. (2017). Their two depleted MORB samples are aberrantly super-chondritic. Although we can replicate their lowest  $\delta^{98/95}$ Mo (-0.05‰ for enriched 308 MORB ALV 518 3-2), in keeping with McCoy-West et al. (2019), we obtain a lower value for 45N 309 (-0.09% vs 0.04‰) and all the other enriched samples of Liang et al (2017) have markedly higher 310  $\delta^{98/95}$ Mo than enriched MORB reported by Bezard et al. (2016) or Chen et al. (2022) (Figure 2). From 311 the resulting mean depleted and enriched MORB  $\delta^{98/95}$  Mo (Table 1) and weighted by the proportion of 312 Mo derived from depleted and enriched ridge segments, we obtain a global mean  $\delta^{98/95}$ Mo of 313 -0.18±0.01‰ for the melts of the upper mantle. While we recognise that the still limited Mo isotope 314 database makes such a value provisional, it is formally resolved from the chondritic reference. Given 315 the effects of melting (section 5.2), the  $\delta^{98/95}$ Mo of the upper mantle itself is ~0.02‰ lower than this 316 317 average MORB value, i.e. -0.20±0.01‰.

Previous studies have examined the  $\delta^{98/95}$ Mo of the Archaean mantle from analyses of komatiites 318 (Greber et al., 2015 and McCoy-West et al., 2019). This dataset is highly variable and further spans to 319 320 Ce/Mo considerably higher and lower than values of modern, unaltered magmas derived from the mantle (Figure 5). These observations are unsurprising as all komatiites are to some extent altered and 321 metamorphosed and Mo is a fluid mobile element during both processes. Filtering for perturbation, 322 using Mn/Fe<sup>2+</sup> and Al/Fe<sup>2+</sup> but not Ce/Mo, McCoy-West et al. (2019) identified nine less altered 323 komatiites, none of which have  $\delta^{98/95}$ Mo outside uncertainty of the chondritic value (see samples in 324 circles in Figure 5). The mean for these komatiites is statistically sub-chondritic only by considering a 325 standard error of the mean of these samples, but these komatiites are quite unrelated to one another and 326 327 do not obviously form part of the same population, not least given their variable <sup>142</sup>Nd/<sup>144</sup>Nd (Caro and Bourdon, 2010; Debaille et al., 2013) and <sup>182</sup>W/<sup>184</sup>W anomalies (Puchtel et al., 2018; Touboul et al., 2012). We think that the significance of the McCoy-West et al. (2019) mean Mo isotope composition for the Archaean mantle should therefore be treated with caution, particularly at the precision cited. In contrast to the modern case explored above, where 19 out 42 depleted MORB have significantly subchondritic  $\delta^{98/95}$ Mo, only one out of 28 komatiites is resolvably sub-chondritic and this one sample did not pass the filter for weathering employed in McCoy-West et al. (2019).

334

# 335 5.4 Mechanisms for lowering the Mo isotope composition in Earth's mantle

The existence of mantle domains with  $\delta^{98/95}$ Mo lower than chondrites is geologically relevant 336 because experimental studies imply that equilibrium fractionation during core formation cannot enrich 337 the mantle in light Mo isotopes (Hin et al., 2019, 2013). A putative Hadean sulphide matte of ~0.2 wt% 338 of the mantle (O'Neill, 1991) would not have significantly affected the Mo isotope composition of a 339 post-core formation mantle (see Figure 3b for sulphide extraction effects), which Hin et al. (2019) 340 estimated to be  $0.01\pm0.02\%$  heavier than the  $\delta^{98/95}$ Mo of  $-0.15\pm0.01\%$  for the bulk Earth. A different 341 process must thus have occurred that lowered a post-core formation  $\delta^{98/95}$ Mo from an estimated 342  $-0.14\pm0.02\%$  to an estimated  $-0.20\pm0.01\%$  in Earth's modern mantle. 343

344

### 345 *5.4.1 Isotopically light Mo in melted residual mantle*

346 McCoy-West et al. (2019) argued that melting very likely results in Mo isotope fractionation. Although no experiments have yet been performed to confirm these theoretical calculations, empirical 347 support for this idea may be found in the work of Chen et al. (2022). This study accounted for 348 correlations of  $\delta^{98/95}$ Mo with (La/Sm)<sub>N</sub> in MORB and seamount lavas as the result of Mo isotope 349 350 fractionation by small degree (<2%) melting of depleted mantle. Chen et al. (2022) argued that such small degree melts migrated into the oceanic mantle lithosphere, were recycled with it and remained 351 isolated sufficiently long (~1 Ga) to further evolve radiogenic isotopic signatures appropriate for 352 enriched MORB. The magnitude of Mo isotope fractionations required by this model are consistent 353 with those predicted by McCoy-West et al. (2019). 354

A corollary of isotopically heavy Mo in melts is that the residue becomes isotopically light. At 355 high degrees of melting, such as for MORB, the majority of an incompatible element such as Mo will 356 357 be concentrated in the melt. By mass balance, high degree melts must closely represent the initial mantle composition and the Mo depleted residue is perturbed to lighter  $\delta^{98/95}$ Mo than its starting composition. 358 359 In this way, McCoy-West et al. (2019) argued that the sub-chondritic  $\delta^{98/95}$ Mo they inferred for Archaean mantle resulted as a complement to early, continental crust formation. From a simple Mo 360 isotope mass-balance, they inferred an Archaean proto-continental crust at least as large as the current 361 continental volume to account for the sub-chondritic  $\delta^{98/95}$ Mo in Archaean mantle. 362

As discussed in section 5.3, we believe it is premature to characterise the  $\delta^{98/95}$ Mo of the Archaean 363 mantle as sub-chondritic using the current komatiite dataset. Nonetheless, the modern, depleted mantle 364 may still reflect the consequences of magmatic Mo fractionation during the extraction of the continental 365 crust. There are two important problems with such a model. As noted by McCoy-West et al. (2019), it 366 is difficult to reproduce the best estimate for modern continental crust ( $\delta^{98/95}$ Mo ~0.1‰; Yang et al., 367 2017) in simple melting scenarios. Given its incompatibility, most mantle melts are enriched in Mo and 368 by mass balance their  $\delta^{98/95}$ Mo must lie close to their initial, unmelted mantle value, so it is the depleted 369 residual mantle that becomes isotopically light rather than the melt complement becoming significantly 370 371 heavier in its Mo isotope signature. McCoy-West et al. (2019) acknowledged this problem and argued for repeated remelting of the crust to increase continental  $\delta^{98/95}$ Mo. To have a net effect on continental 372 composition, however, a substantial fraction of Mo needs to be accommodated into mafic cumulates 373 374 that are delaminated back to the mantle.

A potentially more important consideration is that the modern, depleted mantle has several distinctive trace element ratios, e.g. high U/Th, Nb/U, Ce/Pb that are complementary to the modern continental crust, but cannot be a result of simple magmatic processes, during which the elements in these ratios show similar incompatibility (e.g. Hofmann, 1988). Element fractionations associated with plate recycling and subduction zone processes are widely believed to be responsible for these key trace element signatures (Hofmann, 1988; Miller et al., 1994). It therefore makes sense to examine if isotopic fractionation of Mo might be a consequence of the same subduction zone processes.

#### 383 *5.4.2 Subduction zone fractionation of Mo isotopes*

A growing number of studies show that arc lavas have isotopically heavy Mo isotopic 384 compositions. Some argue for a role in fractionation of hydrous phases in generating such elevated 385  $\delta^{98/95}$ Mo (Gaschnig et al., 2017; Voegelin et al., 2014; Wille et al., 2018), but mafic arc lavas, which 386 387 can have experienced minimal fractionation of Mo isotopes due to differentiation, commonly have markedly higher  $\delta^{98/95}$ Mo than MORB (Freymuth et al., 2015; König et al., 2016; Li et al., 2021; 388 Villalobos-Orchard et al., 2020), with an average of  $\sim 0.03\%$ . Such lavas are also characterised by low 389 390 Ce/Mo due to the relative mobility of Mo in fluids, as well as by low Ce/Pb and Nb/U. Therefore, arc lavas have both  $\delta^{98/95}$ Mo much closer to the values of continental crust than simple mantle melts and 391 392 further carry key complementary trace element signatures to balance mantle depletion.

A consequence of isotopically heavy Mo in arc lavas is that the subduction-processed residue must 393 be isotopically light. This has been clearly documented by Chen et al. (2019), who studied Mo isotope 394 compositions in exhumed, MORB-like eclogites and found that they have  $\delta^{98/95}$ Mo as low as -0.7%, 395 accompanied by higher Ce/Mo than MORB. The authors showed this process is driven by retention of 396 isotopically light Mo in rutile and they argued that the isotopically heavy Mo was lost to the arc by 397 transportation in dehydration fluids. They modelled this quantitatively using an experimentally 398 399 determined Mo isotope fractionation factor between rutile and hydrous melt. The fluxing of the subducting slab with fluids also depletes the slab in fluid mobile Pb (Miller et al., 1994) but results in a 400 relative enrichment in Nb, that strongly partitions into rutile, creating an ocean crust residue with low 401  $\delta^{98/95}$ Mo and high Nb/U and Ce/Pb ratio. Recycling of this fluid-fluxed, residual crust back into the 402 mantle can account for the key chemical features we wish to explain. 403

We undertake quantitative assessment of this process in the next section but here briefly clarify our conceptual model. We consider an overall depleted mantle (e.g.  $(La/Sm)_N < 1$ ) complementary to an ancient continental crust. Since the onset of plate tectonics, the continual formation and destruction of oceanic plates makes this reservoir heterogenous, with harzburgitic and basaltic components recycled back into this depleted mantle. The former component dominates volumetrically but the latter is the chief repository of incompatible elements. Although the recycled ocean crust is more enriched than the averaged mantle from which it is derived, we argue that the recycled mafic crust is not the source of enriched MORB, contrary to some studies (Prinzhofer et al., 1989; Yang et al., 2020). The important
feature we highlight is that enriched MORB is characterised by isotopically heavy Mo (Bezard et al.,
2016; Chen et al., 2022), whereas recycled mafic crust is isotopically light (Chen et al., 2019). This
observation makes recycled mafic crust an unlikely contributor to enriched MORB. Instead, we invoke
enriched MORB is generated by addition of a third component in the oceanic lithosphere, i.e. portions
of the harzburgitic lithosphere that have been metasomatized by small degree melts frozen into its base.

All recycled lithosphere will comprise comparable proportions of harzburgite and basaltic crust, 417 418 but the distribution of melts frozen into the base of the lithosphere is likely governed by local upwelling 419 and is not ubiquitous. The three components of recycled lithosphere will become intimately juxtaposed 420 by convective stirring (Allègre and Turcotte, 1986) together with mantle residual to continental extraction that has not yet been processed through the ridge system. We note that the main incompatible 421 element contributors to typical MORB are the recycled, basaltic crust and residual mantle. A full 422 423 compositional range from depleted to enriched MORB further requires variable contributions of melts from the harzburgitic mantle lithosphere and its metasomatized portions, respectively, that are mixed 424 425 within an erupted batch of MORB. Due to the extreme incompatible element depletion of the harzburgitic lithosphere, variability in this component is best fingerprinted using the least incompatible 426 427 Lu-Hf isotopic system (Salters et al., 2011). We argue that the 'all normal MORB' average of Gale et al. (2013) represents the globally averaged melt contributions from the four different lithologies. Our 428 model simply tracks the long-term evolution of this averaged, depleted, reservoir and does not attempt 429 to reproduce any detail created by source heterogeneity. 430

Key to our arguments is the recycling of mafic crust. The modification of this crust during subduction leads to net evolution of the mantle, by loss of fluid mobile elements to the continents. In major element terms, however, the mantle is at near steady state as subduction resupplies a fusable, basaltic component to the mantle to allow continued melting over Ga timescales. The recycled mafic crust is an intrinsic part of this dynamic, but overall depleted mantle, such that the trace element compositions imposed on the recycled crust by subduction become integral to the depleted MORB source.

### 439 5.4.3 Model of molybdenum cycling

In this section we calculate the influence of recycling subduction-processed mafic crust on the 440  $\delta^{98/95}$ Mo evolution of the mantle using a simple mass balance model. We also examine the related 441 evolution of Ce/Pb. We chose Ce/Pb rather than other distinct incompatible element ratios of the 442 modern, depleted mantle, such as Nb/U or Th/U, that have also been argued to result from plate cycling, 443 as Ce/Pb is most closely linked to  $\delta^{98/95}$ Mo, via loss of Pb and Mo during fluid fluxing of the mafic 444 crust. The role of recycling in influencing U budgets is dominantly a result of seafloor alteration and so 445 446 not as easily tied to Mo isotope fractionation in the subduction zone. A quantitative discussion of Ce/Mo 447 in the mantle with time is complicated by the poorly constrained Ce/Mo in the early Earth, which needs to be estimated by accounting for the siderophile behaviour of Mo. 448

The model extracts a mass flux of Mo, Ce and Pb during subduction dehydration over time and stores this flux in the continental crust. We calculate these mass fluxes from modern estimates of global arc production rates, arc length and element contents of arc lavas, and subtract them from the mantle to determine its evolving concentrations of Mo, Ce and Pb. All details are described in the Supplementary Information, including the option to investigate the effect of sediment fluxes to mimic continental crust recycling, but the general form of the equations is given here with the example of the Mo isotope evolution of the mantle:

456 
$$\delta Mo_{dm,t_i} = \frac{M_m C_{dm,t_{i-1}}^{M_0} \delta Mo_{dm,t_{i-1}} - (t_i - t_{i-1}) flux_{arc,t_i}^{M_0} \delta Mo_{dm,t_{i-1}}}{M_m C_{dm,t_{i-1}}^{M_0} - (t_i - t_{i-1}) flux_{arc,t_i}^{M_0}}$$
(1)

where  $M_m$  is the mass of the mantle,  $C_{dm}^{Mo}$  the Mo concentration in the modelled mantle,  $t_i$  is time at time-step *i*, and  $flux_{arc}^{Mo}$  the flux of Mo mass extracted from the mantle at arcs. This example uses data on arc lava compositions to calculate element fluxes, but we also used the contrasting Mo contents and isotopic compositions of MORB and exhumed, MORB-like eclogites to estimate the flux extracted from the mantle over time for the Mo isotope system. Although results for Mo isotope ratios are similar using this alternative approach, it is less suitable for Ce/Pb because this ratio is typically disturbed in eclogites due to late-stage fluid migration (see Supplementary Information for more model details).

464 Figure 6 shows that the modelled mantle gradually obtains a lighter Mo isotope composition as 465 mixing subduction residues with low  $\delta^{98/95}$ Mo into the mantle progresses with time, following preferential removal of heavy Mo isotopes during slab dehydration. It is poorly constrained what proportions of subducting oceanic crust are recycled in the upper mantle or reach the lower mantle. Additionally, the mantle is chemically heterogeneous, implying that chemical mixing is not perfect. In our recycling model, we circumvented these complexities by modelling two end-member scenarios of perfect chemical mixing in either the whole mantle or the upper mantle, the upper mantle referring to the mass of the mantle above the seismic discontinuity at 660 km depth. We compare these model results to the mean  $\delta^{98/95}$ Mo of  $-0.20\pm0.01\%$  we determined in section 5.3 for the upper mantle.

473 If all subducting oceanic crust is recycled into the upper mantle (red lines in Figure 6),  $\sim 1.1$  Gyr of subduction lowers the  $\delta^{98/95}$ Mo to a value of -0.20‰, while simultaneously increasing Ce/Pb to the 474 value of ~30 estimated for the upper mantle (Workman and Hart, 2005). If all subducted oceanic crust 475 is homogenised into the whole mantle, this timescale increases to  $\sim 3.9$  Gyr (black lines in Figure 6). 476 Recycling 10% of a subducting sediment layer of globally averaged thickness into the upper mantle 477 (Figure 6, broken, red curve) slightly increases the model timescales to ~1.4 Gyr for both  $\delta^{98/95}$ Mo and 478 Ce/Pb. This sediment fraction is equivalent to 0.5% of sediment in the recycled oceanic crust, which 479 480 falls within the range of 0-2.2% sediment in the mixtures of recycled crust and depleted mantle modelled by Chauvel et al. (2008) that successfully reproduced the Hf-Nd isotope array of MORB. The timescales 481 482 considered for the upper mantle scenario are within recent estimates for the duration of modern plate tectonics (e.g. Dhuime et al., 2012) and the great oxidation event. Prior to that time the compositions of 483 modern arc lavas and eclogites we used to estimate chemical fractionation during slab dehydration may 484 not be applicable due to changing redox conditions in subduction zones. The longer timescales in the 485 whole mantle recycling scenario appear to require an additional process to aid in lowering the mantle's 486  $\delta^{98/95}$ Mo and increasing its Ce/Pb, or alternatively imply that mixing is not uniform throughout the whole 487 mantle. Nonetheless, our simple attempt at quantifying the influence of subducting oceanic crust on the 488 489 composition of Earth's depleted mantle implies that this process can simultaneously account for the high Ce/Pb and low  $\delta^{98/95}$  Mo observed in many depleted MORB. Mo isotope fractionation during partial 490 melting could aid in lowering  $\delta^{98/95}$ Mo of the residual mantle, but not in substantially increasing its 491 492 Ce/Pb (Figure 6).

### 494 6 Conclusions

495 We document that depleted MORB commonly have resolvably sub-chondritic Mo isotope compositions. For the upper mantle as a whole, we estimate  $\delta^{98/95}$ Mo = -0.20±0.01‰, which is also 496 sub-chondritic. Prior work has established that core formation cannot account for a sub-chondritic 497 498 mantle  $\delta^{98/95}$ Mo. We argue against melt fractionation of Mo isotopes as the dominant cause for low  $\delta^{98/95}$ Mo in the upper mantle (McCoy-West et al., 2019), as this process does not readily account for 499 associated, diagnostic trace element fractionations (e.g. Ce/Pb) nor current estimates of the  $\delta^{98/95}$ Mo of 500 501 continental crust. We propose that subduction-processed mafic crust, which previous work has shown 502 to have isotopically light Mo (Chen et al., 2019) and high Ce/Pb (Miller et al., 1994), remixed back into 503 the upper mantle can better account for current observations. In a simple model we quantitatively show that such a process can impart the requisite chemical signatures over a few billion yeas of plate tectonic 504 cycling. Notwithstanding its chemical heterogeneity, our work implies that the ambient mantle most 505 506 commonly sourced during MORB melting is a mixture of mantle complementary to an ancient 507 continental crust and subducted ocean crust.

Figure 1. Radiogenic isotope compositions of mid-ocean ridge basalts (MORB) studied for  $\delta^{98/95}$ Mo<sub>NIST SRM 3134</sub>. a) <sup>143</sup>Nd/<sup>144</sup>Nd against <sup>87</sup>Sr/<sup>86</sup>Sr, b) <sup>206</sup>Pb/<sup>204</sup>Pb against <sup>87</sup>Sr/<sup>86</sup>Sr. Samples from the Pacific Ocean are depicted as diamonds, the Atlantic Ocean as circles and the Indian Ocean as triangles. Symbols with a cross represent enriched MORB with (La/Sm)<sub>N</sub>>1. Compilation of mid-ocean ridge basalt data from PETDB repository based on a search for volcanic basalts from spreading centres. Note that a few of these repository data plot outside the scale of both panels. Note that depleted Indian MORB have a DUPAL-like signature typical of MORB from this ocean basin.

Figure 2. Mo isotope compositions of mid-ocean ridge basalts against their chondrite-normalised La/Sm. Samples from the Pacific Ocean are depicted as diamonds, the Atlantic Ocean as circles and the Indian Ocean as triangles. Symbols with a cross represent enriched MORB. Note that three depleted MORB of Liang et al. (2017) and two of Bezard et al. (2016) with anomalously high  $\delta^{98/95}$ Mo are excluded from further discussion in our present study (see main text for further discussion). The mean  $\delta^{98/95}$ Mo<sub>NIST SRM 3134</sub> estimated for the bulk Earth is shown by the black line, with the grey field representing its 95% confidence interval (Burkhardt et al., 2014; Liang et al., 2017).

Figure 3. a) Mo isotope compositions observed in experiments that equilibrated silicate liquid with sulphide liquid at 1.5 GPa and 1400°C, plotted as a function of experimental run duration. The black line and shaded rectangle depict the measured  $\delta^{98/95}$ Mo<sub>NIST SRM 3134</sub> and its uncertainty in MoO<sub>2</sub> powder used in the starting mixture. b) Modelled Mo isotope evolution of residual silicate liquid as a function of sulphide extraction following Rayleigh fractionation. The initial  $\delta^{98/95}$ Mo<sub>NIST SRM 3134</sub> of -0.15% in the modelled silicate liquid is based on the estimated Mo isotope composition of the bulk Earth. The modelling was performed assuming an equilibration temperature of 1200°C between sulphide and silicate liquids using a Mo isotope fractionation factor of -0.32%, adapted from our experimentally determined fractionation factor assuming proportionality to the square of temperature. We used a value of 23 for the sulphide/silicate partition coefficient of Mo, based on the experiments we performed for this study.

Figure 4. Mo isotope compositions of mid-ocean ridge basalts from this study plotted against their  $(^{234}\text{U}/^{238}\text{U})$ . Arrow illustrates effect of mixing between an uncontaminated melt and Fe-Mn crust. "Plus" marks and values along the arrowed mixing line indicate mass fraction of Fe-Mn crust in the mixture. Note that several samples are resolved from the mixing line, indicating that their sub-chondritic Mo isotope composition cannot be explained by contamination with Fe-Mn crust. Composition of the melt used in the mixing calculation:  $\delta^{98/95}\text{Mo}_{\text{SRM3134}} = -0.15\%$ , estimated bulk Earth composition based on the mean of representative chondrites and iron meteorites in Burkhardt et al., 2014, and Liang et al., 2017; Mo content =  $0.3 \ \mu g \ g^{-1}$ , based on mean for MORB in this study;  $(^{234}\text{U}/^{238}\text{U}) = 1$ ; and U content =  $0.055 \ \mu g \ g^{-1}$ , based on the mean for D-MORB in Gale et al., 2003. Composition used for Fe-Mn crusts:  $\delta^{98/95}\text{Mo}_{\text{SRM3134}} = -0.92\%$  and Mo content =  $477 \ \mu g \ g^{-1}$  (Siebert et al., 2003);  $(^{234}\text{U}/^{238}\text{U}) = 1.144$  and U content =  $13.1 \ \mu g \ g^{-1}$  (Henderson and Burton, 1999).

Figure 5. Mo isotope compositions of depleted mid-ocean ridge basalts (grey; this study, Bezard et al., 2016, Chen et al., 2022) and komatiites from Greber et al. (2015; orange) and McCoy-West et al. (2019; magenta), plotted against their Ce/Mo. The estimated  $\delta^{98/95}$ Mo of the bulk Earth is shown as a black line with the grey field representing its 95% confidence interval. Samples in circles have been used by McCoy-West et al. (2019) to derive a  $\delta^{98/95}$ Mo in the Archaean mantle, based on filtering the komatiite data set for weathering effects using their Mn/Fe<sup>2+</sup> and Al/Fe<sup>2+</sup>. All data have 2s uncertainties. The relatively large uncertainties on the komatiite data are likely due to lower measurement intensities caused by the low Mo contents in komatiites.

Figure 6. Modelled Mo isotope compositions and Ce/Pb evolution of the mantle. The modelled mantle following oceanic crust subduction into the whole mantle (black line) or into the upper mantle (red line) is shown with tick marks indicating the time of continued subduction in Gyr. Broken lines depict model results in which the subducted slab contains 0.5% (by weight) sediment (see text and Supplementary Information for details). The modelled compositions of melt (brown curve) and residue (green curve) following mantle melting are depicted with melt fractions from 0.2% to ~15% (cpx-out). Subduction lowers the Mo isotope composition of the modelled mantle as processing of oceanic crust in subduction zones enriches the residue in light Mo isotopes and in Ce relative to Pb, storing their complements (similar to arc lavas) in continental crust. This model runs through the estimated composition of the modern (depleted) MORB mantle with  $\delta^{98/95}$ Mo from our study and Ce/Pb from Workman and Hart (2005). Top-right inset focusses on the results of this model to better display the individual curves (note that to this effect, the curve for the whole mantle including 0.5% sediment recycling is not shown.) As mantle melting barely fractionates Ce/Pb, modelled melt does not approach modern arc lava or continental crust compositions, nor does a modelled melt residue approach the modern MORB mantle composition. Compositions of the various reservoirs are depicted here by their mean with 95% confidence interval on their  $\delta^{98/95}$ Mo and 1s uncertainty on their Ce/Pb. See Supplementary Information for individual compositions of reservoirs.

Table 1. Results of mid-ocean ridge basalts and and liquid sulphide – liquid silicate experiments. depl. = depleted.

<sup>1</sup>La/Sm normalised to a chondritic La/Sm of 1.57.

<sup>2</sup>Standard deviations based on long-term reproducibility of geological reference material W2a are given for all individual samples of mid-ocean ridge basalt, as their number of repeated analyses are  $\leq 3$ . Uncertainties for experiments as well as for ocean basin means are 95% confidence intervals calculated as s/sqrt(n)\* $t_{0.95}$  where s is the standard deviation based on the relevant samples and  $t_{0.95}$  is the value for a two-sided Student *t* - distribution with 95% confidence region.

<sup>3</sup>Concentration-weighted mean of MORB with  $(La/Sm)_N < 1$  in this study, Bezard et al. (2016) and Chen et al. (2022), excluding two outliers in Bezard et al. (2016).

<sup>4</sup>Concentration-weighted mean of MORB with  $(La/Sm)_N > 1$  in this study, Bezard et al. (2016) and Chen et al. (2022).

<sup>5</sup>Samples were not leached.

Table 2. Compositions (wt%) of silicate glass and sulphide determined gravimetrically (starting mixture) or by electron microprobe, except for Mo contents in KK29-1 glass and sulphide, which were determined by isotope dilution with a double isotope tracer.

<sup>1</sup>Mo was added to the starting mixture as MoO<sub>2</sub>.

 $^{2}$ Mo concentrations in KK29-1 glass and sulphide were determined by double-spiked isotope ratio analysis. They have been given an estimated 2% relative uncertainty based on the small sample masses of a few mg.
