## 26 **Abstract**

27 Advances in network ecology offer new tools for the sustainable management of  
28 agroecosystems. Plants in field margins may be involved in different processes of agronomic  
29 importance - indirectly affecting crops by supporting shared pollinators, hosting natural enemies  
30 of pests or acting as pest reservoirs. In this work, we explored the use of motifs (patterns of  
31 interaction between a subset of species) in agricultural ecological networks incorporating  
32 multiple types of trophic interactions to identify plant species with a key role in field margins. We  
33 searched for plant species benefiting crops via (1) shared pollinators and (2) supporting  
34 parasitoids of crop pests; or (3) negatively affecting crops through attracting pest herbivore  
35 species. We focused on determining whether species' showed consistent affiliation with these  
36 roles across the landscape and evaluated the potential of plant species to influence crops  
37 indirectly via shared insect partners. To showcase our framework, we used a unique data set of  
38 antagonistic and mutualistic interactions recorded in soybean crops and wild plant species in  
39 field margins, that despite its limitations (e.g., spanning one growing season) allowed us to test  
40 our approach using multiple types of interactions simultaneously. Here, we support the use of  
41 motifs in multi-trophic interaction networks in agroecosystems to reveal the role of key plant  
42 species in sustaining ecological functions involving crops and other plant species, enhancing  
43 the evidence base for management recommendations in the future.

44 **Keywords:** Indirect interactions; Multi-trophic networks; Pollination; Pest control; Herbivory.

45

## 46 **1. Introduction**

47 Non-crop plants in field margins (e.g., hedgerows or flower strips) are essential for  
48 biodiversity conservation, sustainability and functioning in agro-ecosystems (Albrecht et al.,  
49 2020; see definition in Supplementary Material 1). A significant mechanism by which they affect  
50 crops is through spillover effects (i.e., cross-boundary movement of individuals; Rand et al.,

51 2006; Supplementary Material 1). Via these reciprocal transfers plants may indirectly benefit the  
52 surrounding crops via bottom-up effects on their shared partners, e.g., increases in flower-visitor  
53 or parasitoid abundance leading to increased pollination and biological control. However, the  
54 same plants might negatively affect crops by attracting agricultural pests (Bianchi et al., 2006;  
55 González et al., 2016).

56 Plants are embedded in complex networks of interactions (Pocock et al., 2012) through  
57 which they can affect other organisms via a number of direct and indirect pathways (Bohan et  
58 al., 2013). A useful approach to capture this complexity is merging different types of interactions  
59 into a single multi-trophic network (Fontaine et al., 2011; Pocock et al., 2012; Supplementary  
60 Material 1). This is particularly relevant in agroecosystems considering plant multi-functionality  
61 and the potential trade-offs between positive and negative effects of maintaining surrounding  
62 natural vegetation on field margins (Windsor et al., 2021). By constructing these networks, it is  
63 possible to investigate the roles of species' involved in multiple different ecological processes.

64 Motifs, are the building blocks of larger networks formed by at least two species  
65 (Simmons et al., 2019), and can be used to track the role of species in networks and measure  
66 their prevalence across ecological communities (e.g., McLeod et al., 2020; Baker et al., 2015;  
67 Supplementary Material 1). Additionally, motifs allow for the detection of certain species that  
68 have high fidelity to their ecological role by consistently occupying the same position in networks  
69 (e.g., hosts and parasitoids interacting in the same way across time and space; Baker et al.,  
70 2015). Moreover, motifs are particularly useful for understanding indirect interactions occurring  
71 in ecological communities (Simmons et al., 2019; Supplementary Material 1), such as those that  
72 occur between plants on field margins and their adjacent crops. Knowing how network structure  
73 and species roles' influence ecosystem functioning is fundamental for advancing crop  
74 management in a biodiverse landscape (Bohan et al., 2013).

75 We studied a soybean crop-margin system in central Argentina using multi-trophic  
76 networks, composed of different types of antagonistic and mutualistic interactions (pollination,  
77 herbivory and parasitism interactions), to identify plant species in field margins with key roles  
78 relevant to agronomic management. We applied a network motif approach to assess the  
79 potential trade-offs between different roles of species and whether the species roles remained  
80 constant across different fields, potentially offering ecosystem services or disservices at the  
81 landscape scale. We specifically addressed three questions: i) Can motifs be used to detect  
82 plant species in field margins involved in key agronomical processes? ii) Do species show a  
83 consistent affiliation with certain roles across the landscape? iii) What is the potential of key  
84 species to influence crops indirectly?

85

## 86 **2. Materials and methods**

### 87 *2.1 Applying motifs in multi-trophic networks from a Soybean-margin system*

88 We studied a soybean-margin system from the Pampas, the main agricultural region in  
89 Argentina. We used a species interaction dataset from a field experiment carried out in the  
90 vicinity of "San Claudio" ranch in Buenos Aires (36° 00' S, 61°5' W) during the soybean  
91 flowering season in January 2018. We use data from 20 soybean plots to construct 20 multi-  
92 trophic networks involving mutualistic and antagonistic species interactions linking together  
93 soybean crops (*Glycine max* L.), plant communities in their field margins, pollinators (Diptera,  
94 Hymenoptera and Lepidoptera), herbivores (Lepidoptera caterpillars), and their parasitoids  
95 (Hymenoptera and Diptera) (the study system and data collection is described in more detail in  
96 Supplementary Material 2). Although this dataset had limitations (e.g. short period of time  
97 surveyed in one year; see Discussion), it provides a unique opportunity to test the utility of  
98 motifs as it consists of multiple types of interactions.

99

## 100 2.2. Key species in motifs

101 We used three motifs of agronomic interest, revolving around pollination, herbivory and  
102 parasitism, to identify key plant species roles on each multi-trophic network at each plot studied  
103 (Fig. 1). Pollination and herbivory motifs consisted of three taxa: a crop plant, a plant species  
104 from the field margin and a shared insect (pollinator or herbivore, depending on the type of  
105 motif). Parasitism motifs involved five taxa: a crop plant, a pest herbivore of the crop plant, a  
106 plant species from the field margin, a non-pest herbivore interacting with the non-crop plant and  
107 a shared parasitoid interacting with both the crop herbivore and the non-pest herbivore (Fig. 1).  
108 We searched the networks for the selected motifs and extracted the plant species identity and  
109 the number of times the plant occurred in each of the motifs across the different field sites (R  
110 code is available at [github.com/Royal-Society-Agricultural-Networks/multitrophic-networks-](https://github.com/Royal-Society-Agricultural-Networks/multitrophic-networks-motifs)  
111 motifs).

112

## 113 2.3. Fidelity of species to their role

114 In each plot, the roles of each plant species were defined as a vector, in which each  
115 element is the number of times the species is recorded in a given motif. For example, the role of  
116 species “a” in plot “5” is  $f_{a,5} = \{3,1,0\}$ , corresponding to their incidences in pollination (3),  
117 herbivory (1), and parasitism (0) motifs, respectively. As a way to quantify fidelity of species to  
118 their roles, we evaluated if plant species were significantly associated with the different motifs  
119 studied across plots performing a non-parametric permutational multivariate analysis of variance  
120 (PERMANOVA; Anderson, 2001). For the PERMANOVA, we used a Bray-Curtis dissimilarity  
121 matrix of species’ roles in plots as the response variable and the species identity as the  
122 grouping factor (4999 permuted values for the null distribution). We used the “adonis” function  
123 from the “vegan” package (Oksanen et al., 2020). See Supplementary Material 3 for a detailed  
124 version of the methods.

125

#### 126 2.4. Potential for indirect effects

127 We evaluated the indirect interactions between a plant from the margins and the crop via  
128 shared partners, using the species composition of the different studied motifs. To do so, we  
129 estimated the potential for indirect interactions (PII, *sensu* Tack et al., 2011; Müller and Godfray,  
130 1999). The index considers that if two species share consumers (e.g., pollinators), the host  
131 species (acting plant) that has more shared individuals (consumers) would have higher indirect  
132 impact on the other species (target plant). In this study, for each plot we obtained values of PII  
133 for each plant species from the margin participating as both an acting plant and a target plant  
134 when interacting with the crop. We estimated PII using the “PAC” function available in the  
135 “bipartite” package (Dormann et al., 2008). We compared the obtained values as target and  
136 acting plant between species to assess for the balance of interactions in motifs between the  
137 margin and the crop. To do so we implemented Linear Mixed Effect Models using the “nlme”  
138 package (Pinheiro et al., 2021). All analyses were performed using R 3.6.1 (R Core Team  
139 2019). An extended version of the methods is available in Supplementary Material 4.

140

### 141 3. Results

142 In 15 of the 20 multi-trophic networks at least one motif was detected. The pollination  
143 motif was the most represented in the studied plots (N = 14), followed by the herbivory motif (N  
144 = 5; Supplementary Material 5). The parasitism motif was not registered at any plot, i.e., no  
145 parasitoids were shared between a pest host in the crop and a host in the margins. Moreover,  
146 species identities were significantly related to the different key roles studied, with the subset of  
147 plant species related to pollination motifs being different from those composing herbivory motifs  
148 (PERMANOVA:  $F_{7,25} = 9.942$ ,  $p < 0.001$ ).

149           Regarding indirect effects, measured as PII, when we compared the values of individual  
150 species as target and acting roles at each plot, we found varied responses in pollination motifs.  
151 *Eryngium* sp. showed a tendency to higher values as an acting than as a target plant, i.e., a  
152 source of pollinators to the crop rather than a sink ( $F_{1,2} = 9.950$ ,  $p = 0.088$ ). Conversely,  
153 *Hirschfeldia incana* acted primarily as a target species, receiving pollinators from the crop ( $F_{1,4} =$   
154  $7.578$ ,  $p = 0.051$ ). Other species, such as *Melilotus albus* and *Carduus acanthoides* did not  
155 have differences in their role as target or acting plants ( $F_{1,8} = 1.568$ ,  $p = 0.246$  and  $F_{1,6} = 0.260$ ,  
156  $p = 0.629$ , respectively). In herbivory motifs, *Conyza* sp., the only plant species assessed  
157 showed higher values playing a role as target plant, receiving herbivores from the crop ( $F_{1,2} =$   
158  $19.639$ ,  $p = 0.047$ ).

159

#### 160 **4. Discussion**

161           Studying motifs in multi-trophic networks is a useful approach to assess key plant  
162 species in field margins and their potential to be involved in different agronomical processes. To  
163 demonstrate our perspective, we explored multi-trophic networks from soybean crop-margin  
164 systems and detected different plant species distinctly involved either in pollination or in  
165 herbivory motifs. However, we did not detect parasitism motifs, with no plant species in margins  
166 observed supporting parasitoids of crop pests. The commonness of pollination motifs could be  
167 explained by the presence of super generalist species (such as *Apis mellifera* L. and *Palpada*  
168 sp. Macquart) associated with numerous plant species leading to an increase in the number of  
169 interactions and consequently the number of pollination motifs (see Supplementary Material  
170 Table S5.2). Conversely, the absence or a low number of parasitism and herbivory motifs could  
171 be related to species rarity and the high interaction intimacy with their hosts, which could reduce  
172 the occurrence of interactions (Valladares et al., 2012, Tylianakis and Morris 2017). Moreover,

173 more complex motifs with high number of species and interactions are in general less frequent  
174 than more simple ones, such as three species motifs (Simmons et al., 2019).

175         Motifs allowed us to identify that plant species in the field margins exhibited differential  
176 fidelity to the investigated roles. This highlights the importance of considering the use of a pool  
177 of plant species to design multifunctional margins, allowing to supply multiple ecosystem  
178 services while minimizing the disservices (Power 2010; Windsor et al. 2021). Moreover, we  
179 observed many plant species playing the same role (i.e., occupying the same position in motifs),  
180 mainly in pollination motifs, across the studied plots. This is relevant since the diversity (i.e.,  
181 redundancy) in the resources offered to consumers (e.g., pollinators) could help maintain  
182 ecosystem functionality in these highly simplified systems.

183 Studying motifs enabled us to assess indirect interactions, capturing the potential of these  
184 plants to influence crops via shared partners. We observed, especially for pollination motifs, that  
185 plants from margins show different trends in their potential to indirectly impact the crop. This  
186 suggest that the different plant species could differentially benefit the adjacent crops acting as a  
187 source of resources and thus potentially promoting enhanced pollinator visitation in proximal  
188 crops. However, it is important to note that complementary research is needed to determine  
189 changes on tendencies across the time (i.e., phenological changes in the role of the plant in the  
190 network), or which are the processes (facilitation or competition) driving these indirect  
191 interactions (see Carvalheiro et al., 2014).

192         Constructing multi-trophic interactions networks is a challenge, requiring substantial  
193 effort to observe a sizable proportion of the interactions present within an ecosystem. Regarding  
194 the use of our dataset, we recognize several limitations; for example, we measured interactions  
195 over a single year only. Consequently, we may have missed changes in species composition  
196 and relative abundances, as well as changes in interactions between years as a result of  
197 variable biotic and abiotic conditions. Also, surveys were completed over a restricted time span

198 (January), centered on the soybean flowering season. This could restrict the detection of  
199 antagonistic interactions by not sampling other growth stages of plant species that might be  
200 more attractive to herbivores and, consequently, to their parasitoids. Moreover, all these  
201 limitations could result in a low number of recorded motifs and, therefore, a low number of  
202 replicates, reducing the robustness of statistical analyses and comparisons performed with  
203 these data. Despite these limitations, our dataset allowed us to trial the motif-based approach,  
204 which is applicable to different types of interaction or study design, including bipartite networks  
205 (see definitions in Supplementary Material 1). By now, we were able to identify potential  
206 candidates that could improve ecosystem services provided by biodiversity to soybean  
207 plantation. We hope that future studies can develop approaches to optimize the plant sets that  
208 would best benefit plant crops (e.g., Windsor et al. 2021).

209 Bridging the gap between fundamental and applied ecology, network motifs appear to be  
210 a useful tool to aid our understanding of the role of (semi)natural vegetation on agroecosystems  
211 with a view to making management recommendations in the future. To our knowledge, this is  
212 one of the first studies to use multi-trophic interaction networks to study the role of plant species  
213 with potential to influence the provision of different ecosystem services and disservices  
214 simultaneously (but also see Pocock et al., 2012; Windsor et al., 2021). Applying our approach  
215 to different crops and interactions of interest could reveal important ecological data informing  
216 the design of integrative farm-level field margin management strategies. We encourage other  
217 researchers to continue in this way.

### 303 **Figure legends**

304 **Fig. 1.** Ecological definition of motifs of interest of this study (Pollination, Parasitism and  
305 Herbivory) and their agronomic importance. Nodes are species with colors indicating interacting  
306 groups (aquamarine = soybean, green = plants from margin, red = herbivores, yellow =  
307 pollinators, violet = parasitoids), and lines represent links or connections between them. In  
308 circles are detailed the different studied motifs. In addition, we present a glossary with terms  
309 related to the topic of study. Authorship of the taxa images: Thomas Hegna (pollinators) and  
310 Kamil S. Jaron (parasitoid wasp) from <http://phylopic.org/>.

311

## Motifs definition

**Ecological definition:** A plant from the margin sharing pollinators with the crop.

**Agronomic importance:** Spillover effects increasing crop pollination and, in consequence, increasing yields.

**Ecological definition:** A plant species not sharing herbivores but parasitoids with the crop.

**Agronomic importance:** Potential for biological pest control.

**Ecological definition:** A plant from the margin sharing herbivores with the crop.

**Agronomic importance:** Weeds acting as pest reservoirs increase crop damage.
