novel FLP encounter complex, tris-pentafluorophenyl borane-eucalyptol pairing.

## ■ **INTRODUCTION**

Frustrated Lewis pairs (FLPs) have great potential as metal-free catalysts<sup>[1a,b](#page-6-0)</sup> for the activation of small molecules such as hydrogen, carbon dioxide, nitrogen oxides, sulfur dioxide, and olefins[.2a](#page-6-0)<sup>−</sup>[h](#page-6-0) This has led to intensive research into their catalytic potential and properties over the last two decades. For catalytic applications, the nature of the FLP determines the reaction mechanism for the activation of small molecules. The mechanism for small molecule activation, e.g., hydrogen, could involve either preactivation of the small molecule by its association with the Lewis acid (LA) or Lewis base (LB) with concomitant splitting from the other Lewis partner or by the preformation of a LA−LB reactive encounter complex that can then split a small molecule. The strength and steric effects of interactions within Lewis pair components and substrate molecules, through Coulomb forces or molecular orbital overlap, play crucial roles in determining their catalytic reactivity. In an archetypal catalytical cycle of an encounter complex, the electric field model of a FLP considers the pair to be a charged capacitor ([Scheme](#page-1-0)  $1B(I)$ ). Upon the approach of a small molecule, the electric potential energy stored by the FLP can be released, leading to the cleavage of the small molecule and the formation of an ionic complex ([Scheme](#page-1-0) [1](#page-1-0)B(II + III)).[3a](#page-6-0)−[d](#page-7-0) In the case of hydrogen activation, subsequent transfer of the hydride and proton to an acceptor substrate (such as an alkene, imine, or carbonyl species) will allow the hydrogenation of the substrate and restoration of the

frustration energy locked into the FLP-reactive encounter complex.

Within this context, the fine details of what makes a good FLP remain elusive, and FLP design and optimization are still challenging and largely empirical. The structures and electronic profiles of FLPs can be observed by solid-state NMR and X-ray diffraction.[4a](#page-7-0)−[c](#page-7-0) The reactivities of FLPs are currently estimated by the Lewis acidity and Lewis basicity of each individual component or the activation energy calculated using DFT.<sup>[5a](#page-7-0)</sup>

A number of different approaches to characterize FLPs have been attempted and reported in the literature. By NMR spectroscopy, there is no difference in  ${}^{1}H$ ,  ${}^{11}B$ ,  ${}^{19}F$ , and  ${}^{31}P$ spectra between classical FLPs such as  $P(^tBu)_3 \cdot B(C_6F_5)_3$  and  $P(mes)_{3} \cdot B(C_6F_5)_{3}$  and between those of the individual components.<sup>[2b,](#page-6-0)[4b](#page-7-0),[6a](#page-7-0)</sup> The use of <sup>1</sup>H-<sup>19</sup>F HOESY and solidstate NMR techniques is more fruitful and was reported for measuring the intermolecular interaction between FLP components.<sup>[6a](#page-7-0),[b](#page-7-0)</sup> Further NMR studies facilitated with neutron scattering and supramolecular association analysis have been used to study the presence of weakly associated encounter complexes, specifically  $P^tBu_3 \cdot B(C_6F_5)_3$  and lutidine  $B(C_6F_5)_3$

*a* (A) degree of interation between Lewis pair components; (B) is there an observable change in potential across the FLP during catalysis?.

Lewis pairs.<sup>[6c](#page-7-0)−[e](#page-7-0)</sup> Further to this, vibrational spectroscopy<sup>[7a](#page-7-0),[b](#page-7-0)</sup> and UV spectroscopy<sup>7c</sup> have been used to investigate the encounter complexes of FLPs by the teams of Ando and Jupp, respectively.

It occurred to us that given the strong electrostatic interactions between the constituent molecules, it may be possible to directly study (*in actu*) the dynamic interactions between the Lewis pair partners constituting an encounter complex using microwave dielectric spectroscopy (MDS), in which the electric dipole moments thus formed are coupled to the microwave electric field. MDS operates at low power levels (<1 mW, so there is no heating) and is noninvasive, highly precise, and very fast; it could offer the potential of measuring the degree of frustration of the Lewis pairing. Herein, we report our findings on the use of bespoke MDS instrumentation designed specifically to target FLP samples within a suitable host solvent (toluene, which has a relatively small microwave loss).

#### ■ **RESULTS AND DISCUSSION**

**Microwave Dielectric Spectroscopy.** The permittivity (*ε*) of a material is quantified by its electric polarization in response to an applied electric field. This concept is most familiar to synthetic chemists in the measurement and utility of dielectric constants for solvent selection, especially for those being used in microwave reactors. For polar molecules, the largest contribution to *ε* at microwave frequencies is due to the effects of molecular alignment and rotation ([Scheme](#page-2-0) 2A). The polarization of the sample is quantified in terms of the dielectric constant *ε* (more properly *ε*1), which is a measure of the polarization and hence the stored electric potential energy per unit electric field ([Scheme](#page-2-0) 2B). However, coupled with the molecular motion is the energy loss due to the dipole−dipole

relaxation effect, quantified through the loss term  $\varepsilon_{2}$ ; this is most easily thought of as being the frictional energy loss between rotating molecules that are in close proximity with each other [\(Scheme](#page-2-0) 2B). MDS involves the simultaneous measurement of both polarization  $\varepsilon_1$  and loss  $\varepsilon_2$  terms over a typical bandwidth of 0.1−10.0 GHz.<sup>[8a](#page-7-0)-</sup>

We use microwave resonators for MDS owing to their very high resolution for measurement of loss  $(\varepsilon_2)$  in particular and their ability to measure small sample volumes in sealed tubes (since the FLPs studied are highly air sensitive). However, the measurement is restricted to discrete resonant frequencies, so we use the overlapping spectra of a cylindrical cavity resonator (CCR, operating at 2.5, 4.6, 5.7, and 6.8 GHz), a parallel plate resonator (PPR, at 1.0, 2.0, 3.0, and 4.0 GHz), and a hairpin variant of the PPR (known as the HPR) that reduces the frequency further to 0.5 GHz (with harmonics at 1.5, 2.5, and 3.5 GHz). $9a-c$  $9a-c$  $9a-c$ 

All measurements were taken at room temperature (nominally 20 $\degree$ C) with each measurement taking 5 seconds. Within the context of FLP complexes, the analysis of loss  $(\varepsilon_2)$ could provide valuable information about the levels of frustration between a Lewis acid and a Lewis base. Separated Lewis complexes (i, [Scheme](#page-2-0) 2C) will rotate freely with little friction, whereas full Lewis pairs/adducts will rotate as one species, also with little friction (iii, [Scheme](#page-2-0) 2C).

However, we expect that FLP encounter complexes, within which no formal dative bond exists, will rotate independently in very close proximity, causing a high degree of frictional losses, which should be observable as an enhancement of  $\varepsilon_2$  (ii, [Scheme](#page-2-0) 2C). Such strong interactions at the boundary of a Lewis acid and base could be attributed to a reactive encounter complex. $7c,10$  $7c,10$  We anticipate much smaller effects on the polarization  $\varepsilon_1$  since this quantifies the total electric dipole moment of the complexes.

Our focus on the measurement of  $\varepsilon_2$  justifies our use of resonant MDS and, since the relaxation frequency of such a physically large FLP complex is likely to be well below 1.0 GHz, we expect the enhancement in  $\varepsilon_2$  due to friction to grow as the frequency is reduced. Hence, the need for a MDS applicator such as the PPR and its HPR variant, which have low fundamental frequencies (set by their lengths, to which frequency is inversely proportional) but which still allow measurement of small sample volumes, in our case around 0.3 mL, within plugged fluorinated ethylene propylene (FEP) sample tubes. We chose FEP owing to its low chemical reactivity, very low microwave loss, and closely matched  $\varepsilon_1$ value to toluene (2.0 and 2.4, respectively).

**Sample Concentration.** The  $\varepsilon_1$  and  $\varepsilon_2$  values of the empty FEP sample tube, toluene, Lewis acids (in toluene at 0.1 M), Lewis bases (in toluene at 0.1 M), and Lewis pairs (in toluene, each at 0.1 M) were measured across a range of microwave frequencies (0.5−6.8 GHz). Initial measurements explored the influence of sample concentration on permittivity change. As shown in [Figure](#page-3-0) 1A, measurement of  $B(C_6F_5)_3$ , trispentafluorophenyl borane, (pentaF, LA3)-collidine at concentrations of 0.1 M shows a significant enhancement in microwave loss over pure toluene and is a common concentration used for FLPs in catalytic reaction processes. Nonetheless, it is also possible to obtain very precise MDS loss measurements (to a standard error of  $\leq \pm 1\%$ ) at concentrations below 0.01 M.

To optimize the frequency range used for our MDS, a set of measurements were carried out with triaryl phosphines at 1.0,

<span id="page-2-0"></span>Scheme 2. 2.0, 2.5, 3.0, and 4.0 GHz using the PPR and one mode of the CCR. The changes in loss,  $\Delta \varepsilon_2$ , increase as the frequency is reduced, as would be expected for a simple Debye-type relaxation model for the complex, as shown in [Figure](#page-3-0) 1B, and leads us to conduct MDS measurements at 1.0 GHz so as to maximize the differentiation in response to various Lewis pairings.

**Loss Enhancement Measurements (Δ***ε***2).** We performed separate MDS measurements of the loss of the FLP complex  $\varepsilon_{2,\text{FLP}}$ , the Lewis acid  $\varepsilon_{2,\text{LA}}$ , and the Lewis base  $\varepsilon_{2,\text{LB}}$ (all in toluene), and we then calculate the loss enhancement term  $\Delta \varepsilon_2$  using eq 1, taking care to extract the toluene background from each component (summarized visually in Scheme 2E).

$$
\Delta \varepsilon_2 = (\varepsilon_{2,\text{FLP}} - \varepsilon_{2,\text{Tol}}) - (\varepsilon_{2,\text{LA}} - \varepsilon_{2,\text{Tol}})
$$

$$
- (\varepsilon_{2,\text{LB}} - \varepsilon_{2,\text{Tol}}) \tag{1}
$$

Since microwave losses are additive, we expect  $\Delta \varepsilon_2$  to be close to zero for acids and bases that do not interact when mixed, as any loss is associated with dipole interactions between the individual Lewis acid and Lewis base molecules with the surrounding toluene, which will be largely the same as when they are measured in toluene in isolation. However, if frictional loss is present within the FLP complex, then we expect  $\Delta \varepsilon_2$  to be large, increasing at lower frequencies. Hence, we propose that the loss enhancement is a direct measure of the frustration of the FLP complex (Scheme 2E) and can be modeled as a Debye-type relaxation process with a strong intermolecular attraction between the dipoles of large molecules, leading to a relaxation frequency below 1.0 GHz. Our initial measurements of broadband MDS using a coaxial reflectance probe imply a FLP relaxation frequency around 0.1 GHz, though these measurements are invasive and do not offer the high resolution afforded by the resonant MDS as described here.

Proof-of-concept experiments were carried out by measuring the  $\Delta \epsilon_2$  values of FLPs with different Lewis acid components paired with one Lewis base known to be sterically bulky. This method is similar to previous studies on individual FLP components.<sup>[5](#page-7-0)</sup> In this study, Lewis base  $P(mes)$ <sub>3</sub> (LB3) was selected and measured with a range of borane Lewis acids with established Lewis acidity. An enhanced Δ $\varepsilon$ <sub>2</sub> value was obtained, which had a strong positive correlation with increased Lewis acidity ([Figure](#page-3-0) 2).  $11a,b$  $11a,b$  $11a,b$  Mindful of the necessity for dry samples and the potential impact of water on the MDS measurement, we conducted a control experiment. Samples of LA, LB, and FLP were prepared and

measured  $(t = 0)$ , the cap of the three sample tubes was then removed, and the samples were exposed to air atmosphere for 2 days with further MDS measurements on day 1 and day 2 of these "open" samples. The data, provided in the [Supporting](https://pubs.acs.org/doi/suppl/10.1021/jacs.4c02736/suppl_file/ja4c02736_si_001.pdf) [Information](https://pubs.acs.org/doi/suppl/10.1021/jacs.4c02736/suppl_file/ja4c02736_si_001.pdf) document, shows that the MDS response of the LA is (unsurprisingly) dramatically impacted by the air atmosphere, the FLP sample mirrors the LA response, whereas the LB remains largely unchanged. This experiment provides some level of confidence in the absence of water in our samples.

bases,<sup>[1a](#page-6-0),[b](#page-6-0),[12a](#page-7-0)−[d](#page-7-0)</sup> the loss enhancements  $(\Delta \varepsilon_2)$  of Lewis pairs were measured and then calculated using [eq](#page-2-0) 1 and summarized in [Table](#page-4-0) 1a. Note that BPh<sub>3</sub> does not show a strong enhancement (so, we infer, no reactive encounter complex) with any of the Lewis bases tested. This is expected, as without the electron-deficient aryl ring, the borane in  $BPh<sub>3</sub>$  is a very weak Lewis acid.<sup>[13](#page-7-0)</sup> Most 2,4,6-triF (LA2) Lewis acid combinations with Lewis bases show no loss enhancement  $(\Delta \varepsilon_2)$ , with the exception of a weak interaction with the electron-rich  $P(xyl)_3$  and  $P(mes)_3$  (LB2 and LB3) bases. Large  $\Delta \varepsilon_2$  values were found between the strong Lewis acid (LA3) and most of the phosphine Lewis bases tested. The general tendency of B( $C_6F_5$ )<sub>3</sub>, LA3 to give a larger  $\Delta\varepsilon_2$  value with a Lewis base than  $BPh_3$  or 2,4,6-triF is consistent with the Lewis acidity measurement by the Gutmann−Beckett or Childs Methods.[5g,h](#page-7-0) Pairs formed between borane Lewis acids (specifically LA3) and ethereal Lewis bases also demonstrate  $\Delta\varepsilon_2$  values of magnitude similar to those of the phosphine Lewis bases. However, nitrogen Lewis bases (such as pyridine and its methyl-substituted derivatives) currently prove elusive for accurate measurement by this MDS approach. We attribute this, in part, to the propensity of 2-methylated pyridine systems to exhibit tautomeric-type behavior in the presence of borane

**Loss Change during Hydrogen Splitting Δ***ε***2**−**H2 .** Having demonstrated the ability to measure the  $\Delta \varepsilon_2$  values of FLP encounter complexes with high accuracy and discrimination between different combinations of FLP components, we next sought to measure the ability of each combination to split hydrogen using the MDS technique. To collect the required data, the combination of Lewis pairs measured in Table 1a was charged with hydrogen and the change in the loss of Lewis pairs before and after hydrogenation was recorded as  $\Delta \varepsilon_{2-H_2}$ , defined in eq 2. The absolute loss values before and after hydrogenation contain the same (small) background loss of the toluene host, which is subtracted in eq 2. In separate experiments, we have shown that hydrogenation has no effect on the loss of pure toluene.

$$
\Delta \varepsilon_{2-H_2} = \varepsilon_{2,\text{FLP}+H_2} - \varepsilon_{2,\text{FLP}} \tag{2}
$$

Prior to the experiment, it was reasoned that the values of  $Δε<sub>2-H</sub>$ , during the hydrogenation process are likely to be the result of a second type of microwave loss mechanism driven by the microwave electric field that of ionic conduction by the protonated and hydride FLP species formed as products of the reaction (Scheme 3).

<span id="page-5-0"></span>Table 2. Screening for FLP Activity of Eucalyptol Lewis Base: (A) Loss Enhancement (**Δ***ε*2) of Selected Eucalyptol Lewis Pairs,  $(B)$  Loss Enhancement  $(\Delta \varepsilon_{2-H_2})$  for the  $H_2$  Response of Eucalyptol Lewis Pairs, and  $(C)$  Hydrogen Abstraction of Eucalyptol Lewis Pairs

Values of Δ $\varepsilon$ <sub>2−H<sub>2</sub></sub> are summarized in [Table](#page-4-0) 1b. Reactive FLPs are most likely to transfer into a protonated Lewis base [LBH<sup>+</sup>] and hydride-[b](#page-6-0)ound Lewis acid [LA-H<sup>-</sup>].<sup>1a,b,2a,b</sup> The hydrogenated species  $\left[{\rm LB\text{-}H}^{\scriptscriptstyle +}\right] \left[{\rm LA\text{-}H}^{\scriptscriptstyle -}\right]$  are ionic and therefore will generally increase the *ε*<sub>2</sub> value. Since the only factor expected to increase microwave loss during the process of hydrogen splitting is the generation of ion pairs, we propose that changes in  $\Delta \varepsilon_{2-H}$ , can be used to determine the progress and success of the dihydrogen activation reaction. We expect  $\Delta \varepsilon_{2-H}$ , to be proportional to  $\sigma/\omega$ , where  $\sigma$  is the (dc) conductivity of the solution (approximately proportional to the ionic concentration) and  $\omega = 2\pi f$  is the (angular) frequency. Hence, the conduction losses increase with decreasing frequency (as observed experimentally after hydrogenation), and the sensitivity of MDS for loss measurements is increased at lower frequency (in our case, at 1 GHz and below). Here, we are effectively using MDS as a noninvasive, noncontacting measurement of the electrical conductivity of the solutions. The response bars show that Lewis pairs with  $\Delta \varepsilon_2$  values >0.004 are associated with competent hydrogen splitting, delivering Δ*ε*2−H2 values >0.031 or a phase separation (*vide infra*). It is also noted, however, that 2,4,6-triF, in combination with either of the 3 ethereal Lewis bases, affords a negligible  $\Delta \varepsilon_2$  response, but  $\Delta \varepsilon_{2-H2}$ , values ranging from 0.006 to 0.021. This data suggests that either there is hydrogen splitting activity that was not predictable by the  $\Delta \varepsilon_2$  measurement method described here or that the splitting is occurring via a mechanism that does not involve a discrete reactive encounter complex (i.e., likely via a preassociation of LA or LB with  $H_2$ ).<sup>3a,15a−[d](#page-8-0)</sup>

During the running of these hydrogenation experiments, it was noted that a solid precipitate is formed on the introduction of hydrogen gas to the pairing of LA2 (2,4,6-triF) with LB2  $(P(xyl)_3)$ , which we attribute to the corresponding [LB-H+ ][LA-H<sup>−</sup>] ionic species [\(Table](#page-4-0) 1b, marked with a circle). Such a precipitate has a much lower microwave loss compared to the frictional or conduction losses operating on solutions, so the absolute values of these measurements should be discounted. Similarly, in the case of the interaction of LA3 with LB1, 2, and 3, the hydrogenated Lewis pairs form an ionic liquid which separates into a nonmiscible secondary phase ([Table](#page-4-0) 1b, marked with a triangle). A very large increase in  $\varepsilon_2$  was observed upon the formation of this emulsion, and very large values were also obtained with the isolated pure ionic liquids. This observation is consistent with large  $\varepsilon_2$  values previously measured with MDS for ionic liquids.<sup>[16](#page-8-0)</sup> To summarize this behavior, while both the formation of precipitates and ionic liquids lead to inaccurate absolute values by MDS, the very fact that these materials form demonstrates the hydrogen splitting reactivity of these respective Lewis acid and Lewis base pairings.

Notably, strong  $\Delta \varepsilon_{2-H2}$ , values are also observable with ethereal Lewis bases, LB4, 5, and 6 at room temperature. Both ethereal and ketone oxygens have been reported as effective Lewis bases in FLPs for reversible hydrogenation and transfer hydrogenation reactions.[12b](#page-7-0),[17a](#page-8-0)−[c](#page-8-0)

**Correlation of MDS-Measured Δ***ε***<sup>2</sup> Values with <sup>1</sup> H NMR Hydrogen Extraction Reactivity.** Having assessed MDS to measure both Lewis acid/base combinations and their ability to split hydrogen, we sought further verification of the observed trends. Mindful of the propensity for some of these combinations to afford precipitates and ionic liquids, we turned our attention to the process of hydrogen transfer from a model hydrogen donor γ-terpinene and <sup>1</sup>H NMR spectroscopy ([Table](#page-4-0) 1c and [Scheme](#page-4-0) 4). Such a process commonly appears in transfer hydrogenation methods mediated by FLPs.<sup>[18a](#page-8-0),[b](#page-8-0)</sup> In such an experiment, reactive Lewis pairs can extract hydrogen from a dihydrogen surrogate such as *γ*-terpinene, driven by the aromatization of the 1,4-cyclodiene ring, of which both species (starting material and product) can be monitored by <sup>1</sup> H NMR spectroscopy. The response bars of the hydrogen extraction process demonstrate that Lewis pairs with values of  $\Delta \varepsilon_2$  > 0.037 are also associated with competent hydrogen extraction reactivity (>38%, [Table](#page-4-0) 1).

Taken collectively, the data presented in [Table](#page-4-0) 1 demonstrate that MDS is an effective technique for gauging if a Lewis acid/base combination is competent for splitting or abstracting hydrogen, a characteristic property of a frustrated Lewis pair. However, the current capability does not assess if the combination is a competent catalyst (i.e., no on/off or transfer rates for hydrogen have been measured).

**Using MDS to Discover and Develop New FLPs.** To demonstrate the potential of MDS to find new, active FLP combinations, a novel Lewis base (eucalyptol) was examined in combination with the three boranes by MDS and <sup>1</sup>H NMR

<span id="page-6-0"></span>spectroscopy ([Table](#page-5-0) 2). Notably, the ether oxygen of eucalyptol is sterically hindered with a bridged bond angle (C−O−C) of 115° rather than a typical monocyclic (C−O− C) bond angle of  $110^{\circ}$ .<sup>[19](#page-8-0)</sup> Additionally, the two electron-rich tertiary carbon atoms attached to eucalyptol contribute to an increased electron density on the oxygen lone pairs. The data shows that eucalyptol has a moderate  $\Delta \varepsilon_2$  value with LA3 (0.027), congruent with those entries in [Table](#page-4-0) 1a which led to activity for hydrogen splitting and hydrogen abstraction. The MDS data for the eucalyptol−LA3 pair in the presence of hydrogen indeed give rise to a Δ*ε*2−H2 value of 0.152, signifying the splitting of hydrogen. Moreover, treatment of the eucalyptol−LA3 pair with *γ*-terpinene led to the formation of 78% of cymene, demonstrating the ability of the pairing to competently abstract hydrogen (on par with the phosphine− LA3 pairings in [Table](#page-4-0) 1c).

# ■ **CONCLUSIONS**

In conclusion, MDS has been demonstrated as a promising tool for the *in actu* detection of FLP encounter complexes. By measurement and calculation of the net microwave loss  $(\Delta \varepsilon_2)$ , a FLP encounter complex can be detected. Both splitting of hydrogen gas and abstraction of hydrogen from *γ*-terpinene have shown a correlation with those samples with an enhanced microwave loss  $(\Delta \varepsilon_2)$ , pointing toward reactivity through a FLP encounter complex, whereas those combinations with negligible or small  $\Delta \varepsilon_2$  values do not demonstrate an ability to split or abstract hydrogen. This capability led us to postulate a novel FLP in the form of a LA3−eucalyptol pairing. Finally, the accuracy of MDS measurements and the numerical values provided in the microwave loss may point toward the degree of frustration; further work is planned to understand the correlation of these absolute values with catalytic competency and performance.

The manuscript was written through the contributions of all authors. All authors have given approval to the final version of the manuscript.

## **Funding**

This research was funded by a Leverhulme Trust Research Project Grant (RPG-2019-260) and the Engineering and Physical Sciences Research Council (EPSRC EP/W524682/ 1).

# **Notes**

The authors declare no competing financial interest.

# ■ **ACKNOWLEDGMENTS**

The authors acknowledge the financial support from the Leverhulme Trust (RPG-2019-260), the Engineering and Physical Sciences Research Council (EPSRC EP/W524682/ 1). The authors are grateful to Andrew Rankmore and his team in the School of Engineering at Cardiff University for help in the design and construction of all MDS fixtures.
