Abstract. Agglutinated foraminifera are marine protists that show apparently complex behaviour in constructing their shells, involving selecting suitable sedimentary grains from their environment, manipulating them in three dimensions, and cementing them precisely into position. Here we illustrate a striking and previously undescribed example of complex organisation in fragments of a tube-like foraminifer (questionably assigned to *Rhabdammina*) from 1466 m water depth on the northwest Australian margin. The tube is constructed from well-cemented siliciclastic grains which form a matrix into which hundreds of planktonic foraminifer shells are regularly spaced in apparently helical bands. These shells are of a single species, *Turborotalita clarkei*, which has been selected to the exclusion of all other bioclasts. The majority of shells are set horizontally in the matrix with the umbilical side upward. This mode of construction, as is the case with other agglutinated tests, seems to require either an extraordinarily selective trial-and-error process at the site of cementation or an active sensory and decision-making system within the cell.

1 Introduction

Agglutinated foraminifera are unicellular organisms that construct their shells from sedimentary grains gathered from the sea-floor environment and cement them together to form what are sometimes intricate three-dimensional constructions (Brady, 1879; Gooday, 1990). To do this they must select, orientate and secure the grains in ways that are, at present, poorly understood (Allen et al., 1988; Hemleben and Kaminski, 1990; Makled and Langer, 2010; Rothe et al., 2011). The use of grain type can seem relatively haphazard (Armynot du Châtelet et al., 2013) or it can be highly selective of both size and composition. Examples of selectivity include foraminifera that gather specific minerals, sometimes heavy ones, such as ilmenite (Makled and Langer, 2010), rutile (Cole and Valentine, 2006) and garnet (Allen et al., 1999), or particular biological clast types such as sponge spicules (Brady, 1879), echinoderm plates (Heron-Allen and Earland, 1909), or coccoliths (Holbourn and Kaminski, 1997; Thomsen and Rasmussen, 2008). It is also common for some agglutinated foraminifera to re-

use the shells of dead planktonic foraminifera from the surrounding sediment in constructing their tubes (Brady, 1879; Cartwright et al., 1989).

Tube-like agglutinated foraminifera that use planktonic foraminifer shells in their construction are common in bathyal and abyssal environments worldwide, where they live either as suspension or deposit feeders (Gooday, 1990). Fragments are difficult to assign to genus level if the proloculus is absent and the branching pattern unclear, as is the case with the pieces described here. The most important genera that secrete such tubes are *Rhabdammina* Sars (for thick-walled, inflexible, generally branching tubes), *Rhizammina* Brady (for thinner-walled, more elastic tubes which form mat-like clumps), *Hyperammina* Brady (with an enlarged proloculus) and *Bathysiphon* Sars for slowly expanding tubes. The tubes can include mineral grains and foraminifer shells of various species, sizes and orientations that are attached along their length (Brady, 1879; Gooday, 1983; Cartwright et al., 1989).

Figure 1. *Rhizammina algaeformis* Brady: (a, b) modified from Brady 1884, pl. 28, fig. 3 (scales approximately 200 μm and 1 mm); (c, d) specimen from IODP Sample U1482B-mudline. Note the large variation in the size, species, and orientation of the planktonic foraminifer shells along the tube, and the siliciclastic matrix. Foraminifera included in the construction include various species of *Globigerinita*, *Globigerinoides*, *Globorotalia*, *Globoturborotalita*, *Tenuitella*, *Trilobatus*, and *Turborotalita* (scales = 100 μm).

2 Description

Here we illustrate four fragments of what was probably a single tube, which are remarkable because the individual grains belong to a single species of planktonic foraminifer and occur in an organised arrangement. We also show one specimen of *Rhizammina* from the same sample for comparison. The specimens are from International Ocean Discovery Program (IODP) Site U1482 on the northwest Australian margin at 15°3.32' S, 120°26.10' E and 1466 m below sea level, from

the “mudline”, that is, from unconsolidated seawater and sediment slurry from the top of the first piston core taken from the hole (Sample 363-U1482B-1H-mudline).

The *Rhizammina* in the sample is of a type commonly encountered in deep-sea sediments, similar to a paratype of *Rhizammina algaeformis* Brady (Fig. 1). The tube is constructed above an internal organic layer with very fine siliciclastic grains glued together with an organic cement that is not visible in scanning electron microscopy (SEM) but has been described as a probable mucopolysaccha-

Figure 2. A fragment of *Rhabdammina* sp. that uses planktonic foraminifera of a single species in its construction. (a, b) Light microscope and SEM images of the whole specimen. (c) Broken end of tube. (d) Detail of broken end of tube showing wall in cross section. (e) Other broken end of tube. (f, g) Details of external surface. Specimen from IODP Sample U1482B-mudline (all scales = 100 μm).

ride (Cartwright et al., 1989). The shells of planktonic foraminifera, which have been gathered from the surrounding sediment, are set into this siliciclastic matrix. As is normal in *Rhizammina*, the planktonic foraminifer tests are of a wide range of sizes and species. The illustrated example contains a variety of adult and juvenile shells belonging to various genera and species, much as occur in the surround-

ing sediment, although other types of grain such as radiolaria have been avoided. The planktonic foraminifer shells are cemented in apparently random orientations, as has previously been illustrated in this species (Brady, 1879; Cartwright et al., 1989).

The four fragments of *?Rhabdammina* (illustrated as Fig. S1 in the Supplement) are all broken at both ends. The

Figure 3. Particles from the sediment in IODP Sample U1482B-mudline. **(a)** Unattached *Turborotalita clarkei* specimen imaged in umbilical, edge, and spiral views. The umbilical side is distinguished by a deep groove into which the aperture opens. **(b)** General view of the $> 63 \mu\text{m}$ size fraction showing various species of planktonic foraminifer and radiolarians. Three specimens of *T. clarkei* are highlighted with arrows. One other species of *Turborotalita* (*T. quinqueloba*) and many *Tenuitella*, *Globigerinita*, *Globoturborotalita*, and other genera are present (scales = $100 \mu\text{m}$).

largest fragment is a very regular tube, nearly perfectly circular in internal cross section and about 1 mm long with a fairly constant external diameter of about $250 \mu\text{m}$ and an internal diameter of $150 \mu\text{m}$ (Fig. 2). Although polychaetes, nematodes, and crustaceans are all known to construct agglutinated tubes (Gooday, 1990; Finger et al., 2008), the specimens described here can be securely identified as a foraminifer because of the small size and mode of construction which is similar to other agglutinated foraminifera including *Rhizammina* from the same sample. As in *Rhizammina* (see Fig. 1), the tube has a matrix of angular siliciclastic grains into which planktonic foraminifer shells are set.

A total of 123 planktonic foraminifer shells are cemented along the tube of the largest fragment, all of which belong to the single species, *Turborotalita clarkei* (Rögl and Bolli, 1973) (as do the > 100 shells in the smaller fragments). This species is one of the smallest living planktonic foraminifera, spinose in life, with a cosmopolitan distribution (Hemleben et al., 1989). All specimens on the tube appear to be adult, with a diameter of about $100 \mu\text{m}$ and a thick external cortex, which is not always the case in the sediment. The sediment itself contains over 20 species of planktonic foraminifer, among which *T. clarkei* is a relatively frequent but not dominant component among its size class, which also includes

side up, with the umbilical groove in which the aperture is set visible on the outside (104 specimens are umbilical side up versus 14 that are spiral side up and 5 which are on their side). The umbilical-side-up orientation may have been preferred because it avoids having the umbilical groove on the inside, making it easier to construct a smooth inner surface. (The three smaller fragments of tube are also exclusively made of *T. clarkei* with a strong preference for umbilical side upward orientation although the helical pattern is less clear because of the narrower tube diameters; see Supplement.)

Although to our knowledge *Rhabdammina* has not been observed alive, it presumably locates and moves sedimentary grains with its pseudopodial network similar to many other foraminifera. The high degree of grain-type selectivity exhibited by this and other agglutinated foraminifera must be time- and energy-expensive. Once in position at the growing tip of the tube, the grains are presumably cemented in place with an admixture of fine siliciclastic material and secreted polysaccharide cement. The helical arrangement may reflect the growth sequence, in which generally five or six *T. clarkei* shells were located around the growing tip (or fewer when the diameter was narrower), with each new shell being cemented to the left (looking from the outside) of a pre-existing one. Clues to the construction mode come from instances where unusually large or small shells were included, for which there may have been subsequent compensation (e.g. the large specimen D7 in Fig. 4b may have been compensated for by the smaller specimens C8 and E1, moving left to right, and causing a new helical band to start).

3 Discussion

The *apparently* complex behaviour of agglutinated foraminifera has attracted attention since it was discovered in the 1860s and described by W. B. Carpenter (Carpenter, 1873, p. 784) as “most distinct evidence of *selective* power; and the question forces itself upon us, – by what instrumentality is it exercised” (italics and punctuation as in original). Charles Darwin wrote to Carpenter describing it as “almost the most wonderful fact I ever heard of. One cannot believe that they have mental power enough to do so, and how any structure or kind of viscosity can lead to this result passes all understanding” (Charles Darwin letter to W. B. Carpenter, 1873, transcribed in Burkhardt et al., 2014, item DAR 261.6:7). The issue was debated again in 1916, when the foraminifer specialist Edward Heron-Allen claimed it as an example of “intelligence”, which was robustly disputed by the physiologist Edward Ray Lankester in an exchange that quickly became a semantic argument (as described by Hemleben and Kaminski, 1990). But while terms such as “mental power” and “intelligence” remain jarring, the basic problem of how a single cell effects this kind of behaviour remains almost entirely unresolved and the debate has hardly

moved on (Allen et al., 1988; Hemleben and Kaminski, 1990; Makled and Langer, 2010; Rothe et al., 2011).

The phenomenon seems to belong to a different category from cases in which unicellular organisms such as other foraminifera, radiolaria, and diatoms secrete intricate skeletons of silica or carbonate as part of their life cycle (see, for instance, Fig. 3). In those cases the biomineralisation sequence is presumably under genetic and epigenetic control in which information is stored in genes which switch on or off in response to internal triggers. In the case of complex agglutinating behaviour, the correct grain type must be discovered by the pseudopodial network, transported to the precise location required, and then manipulated in three dimensions before being cemented into place. At some point in the process it must be discriminated from other similar grains. We suggest two possible models for how this discrimination occurs. Either (1) it occurs via a highly specific trial-and-error process at the site of cementation to which many grains are brought and rejected, and only *T. clarkei* grains in the correct orientation are accepted, presumably because of having the correct affinity to the binding site, or (2) it occurs in the pseudopodial network wherein only the correct grain type is selected from the sediment and is then moved into position. Both these mechanisms are difficult to envisage, however. The former would be extremely costly and time-consuming whereas the latter demands a sensory system capable of continuously monitoring grain position and orientation plus an information processing ability with decision-making capacity. If such behaviour was exhibited by a metazoan, it would naturally be attributed to the functioning of the nervous system. Observation of living agglutinated foraminifera may help distinguish between these models.

Much behaviour in protists is apparently highly stereotyped and involves chemosensory responses to environmental cues in relation to feeding, predator avoidance, and discriminating clones and potential mates (Vandromme et al., 2010; Harvey et al., 2013). However recent work on partner recognition in some ciliates has concluded that they are able to actively encode, process and respond to information from external pheromone signals which in turn produces planned “courtship strategies” and “social decision making” (Clark, 2013). In the agglutinated foraminifer cell discussed here, the decision-making must also, presumably, have a specialised molecular basis, whether it occurs at the site of cementation or distributed in the pseudopodial network. As far as we know, such processes are obscure, but if they can occur in one type of cell, they could occur in others, so the phenomenon could be more than just a curiosity.

4 Methods

Seawater and sediment slurry from the top of the first piston core at IODP Hole U1482B was collected in a bucket, treated with rose bengal biological stain for 24 h to detect

living cells and washed over 150 and 63 μm sieves. The sample residues were dried on a warm plate at 40 °C. Foraminifer specimens including shells of *Turborotalita clarkei* and fragments of *Rhabdammina* sp. and *Rhizammina algaeformis* were picked by brush and transferred to conductive adhesive discs on metal pedestals for microscopic investigation. Specimens were photographed using a Zeiss Discovery V8 light microscope (LM) and a Hitachi TM 3000 tabletop scanning electron microscope (SEM) in various orientations without conductive coating.

Data availability. The data to this paper can be found in the Supplement.
