Keywords: Evolution, Devonian, Forests, Plant Development
Cladoxylopsida included the earliest large trees which formed critical components of globally transformative pioneering forest ecosystems in the Mid and early Late Devonian (ca. 393-372 Ma). Well known cladoxylopsid fossils include the up to c. 1m diameter sandstone casts known as *Eospermatopteris* from Middle Devonian strata of New York State. Cladoxylopsid trunk structure comprised a more-or-less distinct cylinder of numerous separate cauline xylem strands connected internally with a network of medullary xylem strands and, near the base, externally with downwards-growing roots, all embedded within parenchyma. However the means by which this complex vascular system was able to grow to a large diameter is unknown. We demonstrate, based on exceptional, up to c. 70cm diameter silicified fossil trunks with extensive preservation of cellular anatomy from the early Late Devonian (Frasnian - ca. 374 Ma) of Xinjiang, China, that trunk expansion is associated with a cylindrical zone of diffuse secondary growth within ground and cortical parenchyma, and with production of a large amount of wood containing both rays and growth increments concentrically around individual xylem strands by normal cambia. The xylem system accommodates expansion by tearing of individual strand interconnections during secondary development. This mode of growth seems indeterminate, capable of producing trees of large size and, despite some unique features, invites comparison with secondary development in some living monocots.

Understanding structure and growth of cladoxylopsids informs analysis of canopy competition within early forests with potential to drive global processes.

Significance
The evolution of trees and forests in the Mid - Late Devonian Period, 393-359 million years ago, profoundly transformed the terrestrial environment and atmosphere. The oldest fossil trees belong to the Cladoxylopsida. Their water conducting system is a ring of hundreds of individual strands of xylem (water conducting cells) which are interconnected in many places. Using anatomically preserved trunks, we show for the first time how they could grow to a large size, both by the production of large amounts of soft tissues as well as new wood around the individual xylem strands, and controlled structural collapse at the expanding base. We discovered a tree growth strategy unique in Earth History, but with some similarity to those of living palms.

One of the key episodes in the history of the Earth was “afforestation”, the Devonian transition to a forested planet (1), the development of tree-sized vegetation leading to step changes in the behaviour of sediment on flood plains, clay mineral production, weathering rates, CO$_2$ drawdown, and the hydrological cycle (2, 3). In many ways, this event represents perhaps the most fundamental change in Earth system dynamics between the truly ancient and modern.

The fossil record strongly indicates that the origin of trees was not a solitary evolutionary innovation confined to a single clade. Cladoxylopsid trees appeared first (4) (early Mid Devonian (Eifelian), 393-388 Ma), and then archaeopteridalean and lycopsid trees (late Mid Devonian (Givetian), 388-383 Ma) (5, 6). *Archaeopteris*, an early lignophyte, has the most familiar tree growth strategy, exhibiting extensive secondary development by producing secondary xylem (wood) laid down in concentric growth increments by a cylindrical bifacial vascular cambium (7,
Lycopsids produced limited secondary xylem and expanded their trunk diameter largely by extensive periderm production (9).

Anatomically well-preserved cladoxylopsids known to date, including Pietzschia from the Late Devonian (Famennian, 372-359 Ma) of Morocco (10, 11), probably indicate a primary thickening meristem capable of forming a primary body (and therefore trunks) up to 160 mm across, but demonstrate no secondary increase in diameter. Such plants were likely determinate in growth and limited in size. However Eospermatopteris bases (12) from the older, Mid Devonian (ca. 385 Ma) in situ Gilboa fossil forest (13), NY, USA reached basal diameters of 1 m supporting long tapering trunks (14). The sandstone casts (Fig. 1) reveal coalified vascular strands but only a little preserved cellular anatomy. Thus, despite fragmentary evidence that radially aligned xylem cells in some partially preserved cladoxylopsid fossils may indicate a limited form of secondary growth (4, 7, 11, 15, 16), it remains unclear how this type of plant dramatically increased its girth. We present here exceptionally preserved large trunks from China (Fig. 2, 3) that demonstrate direct evidence how these earliest trees were able to expand their trunk diameter and thereby achieve tree size.

**Results**

Cladoxylopsida

*Xinicaulis lignescens* gen. et sp. nov. Xu, Berry et Stein

**Diagnosis:** Trunk bases with large numbers of individual cauline xylem strands in two concentric, closely-spaced alternating cylinders: attached inwards to anastomosing network of
medullary xylem strands, and outwards to multiple adventitious roots departing downwards from sides of cauline strands; all embedded in parenchyma; extensive central pith in larger trunks; individual cauline strands comprise primary xylem with concentric secondary xylem including rays and growth increments; primary xylem strand of roots terete in transverse section proximally becoming stellate; secondary xylem also present in medullary strands and roots.

**Etymology:** *Xin* referring to Xinjiang and meaning ‘new’ in Mandarin; *caulis* Latin, stem; *lignescens* Latin, becoming woody.

**Holotype.** PB22119 (Fig. 3a).

**Other material.** Two blocks from a 70 cm diameter trunk, PB22120, PB22121 (Fig. 3b, S1a).

**Locality, Age and Horizon.** Bulongguoer Reservoir, Hoxtolgay Town, Xinjiang, Northwest China. Loose blocks, volcaniclastic Zhulumute Formation, Frasnian (Late Devonian) (17) (Fig. S2).

*Xinicaulis* is distinct from *Eospermatopteris* (12) because the cauline xylem strands form a double cylinder rather than a single cylinder.

Our observations are based on two key specimens. The smaller (Fig. 3a), prepared as serial sections (Figs 4, S3), has 29-38 individual cauline xylem strands forming a ring in transverse section ca. 80 mm in diameter, surrounded by a zone of roots in cortical parenchyma up to 32 mm thick, preserved over a length of 100 mm. The larger is a 70 cm diameter trunk (Fig. 2, Figs 3b, S1a) tapering upwards, with the zone of roots up to 10 cm thick, indicating a cylinder of cauline strands of approximately 50 cm diameter (Fig. S1b).
Primary xylem strands consist of radially-directed plates averaging 0.65 mm (small specimen – Fig. 5e) and 2.2 mm (large specimen) in radial extent, and ca. 0.2 mm tangentially. In transverse section, polygonal primary xylem cells are surrounded by up to 17 concentric increments of secondary xylem (Figs 5d, e). Tracheids of secondary xylem are thick-walled and square to rectangular in transverse section with conspicuous pit canals (Fig. 5f). Growth increments in the secondary xylem have up to 13 cells in each file (Fig. 5e). Uniseriate rays (Fig. 5g, h), including some with ray tracheids (Fig. 5i), are present. In the large specimen cauline xylem strands consisting of both primary and secondary xylem average 12.4 mm tangentially, with impressive evidence of large secondary expansion (Fig. 5d).

In the smaller trunk the number of cauline xylem strands increases distally by branching indicating an obconical primary body (Fig. S4). Primary xylem plates are observed to divide radially (Fig. 3a – S, Fig. 5a), but resultant strands become situated in an oblique fashion distally taking on an alternate arrangement in two concentric cylinders (Fig. 3a). We interpret this specimen to represent the trunk very near its base showing upwards increasing size and complexity of the primary body (epidogenetic growth), in this way similar to that previously demonstrated for the base of *Pietzschia* (18). The large specimen appears part of a trunk with an estimated ca. 130 cauline xylem strands (Fig. S1b). This specimen likely represents a more distal part of the basal trunk, where the number of primary xylem plates had increased by further divisions during primary growth.

There is abundant evidence of subsequent modification of the primary body through extensive dilatation (19, 20), or diffusely distributed, growth. Below and above the dichotomies of primary xylem plates normal concentric growth of secondary xylem around the primary xylem plates is observed (Fig. 6b levels *B4, B1*). At the level of the more-or-less equal dichotomy, sub-plates of
the primary xylem are often separated by 2-3mm, with parenchyma and new files of secondary xylem filling the space between them (Figs 5a, 6b level B2). The parenchyma cells are noticeably elongated in the direction of sub-plate separation, indicating relative tension (21) in the tissue between sub-plates (Figs 5a, b, 6f). At the same level the outer surface of the cauline strand, presumably the position of the vascular cambium, remains intact (Figs 5a, 6b level B2, 6d-f, S5f).

Medullary xylem strands (Fig. 3a – M), which both dichotomise and join with other strands distally, show similar formation of elongate parenchyma under tension, including between distally joined strands (Figs 5c, 6g level A7r, S6). Medullary sub-strands often show prodigious numbers of new files of secondary xylem, and form irregular shapes (Figs 3, 5c).

Our interpretation of these observations is that the cauline xylem strands have been physically pulled apart, with resulting splits propagating from the dichotomies and unions both proximally and distally during further development (Fig. 6c, g). This is made possible by proliferating parenchyma, for which there is clear evidence, in regions surrounding the strands and sub-strands. In this context it is interesting to note that cortical and ground tissue parenchyma between cauline xylem strands show variable tension or compression (Fig. 5d), but no systematic crushing of mature primary tissues as might have been expected given the volume of secondary xylem produced (7, 21, 22). All of the evidence therefore strongly suggests that the cauline vascular system and trunk as a whole increased in radial dimension over time in a form of secondary development by means of diffuse secondary growth with parenchyma comprising a large proportion or even the bulk of new tissues produced. The increase in distance between the individual cauline and medullary strands caused by this expansion is therefore most manifest at the interconnections, where it can only be accommodated by physical tearing of the xylem. The
relative number of interconnections in the medullary xylem strands and their complex topology compared to the cauline strands is likely responsible for the more damaged and irregular appearance of the medullary strands, as they have been subjected to a higher incidence of tearing at the nodes.

Tissues interpreted as phloem are incompletely preserved in small patches next to some xylem strands, and have been observed in transverse section only. Some cells are formed in radial files suggesting a secondary origin. This will be subject to further investigation.

Roots originate adventitiously from the outer and tangential surface of secondary xylem growth increments of the cauline strands (Figs 3a - R, 4, 5d, 6g), travel steeply down through an outer zone of parenchyma (Fig. 4), frequently divide (Fig. 3), and display growth increments of secondary xylem (Figs 3, 5d). Primary xylem is small and terete initially, but further from point of origin becomes increasingly stellate (Figs. 3, S1a).

Branch traces are not observed. However many transverse sections of cauline xylem strands show a groove on the outermost surface (Fig. 3, 5d – T) in line with, and as deep as, the primary xylem plate, which may represent disruption to the cambium caused by the presence of branch traces. Evidence of the traces themselves are presumed to have been destroyed at these lower levels by secondary modification of most tissues of the trunk.

Discussion

Our results indicate that the large size of Xinicaulis on a scale equivalent to Eospermatopteris was accomplished by a unique form of secondary development, facilitated primarily by a long-acting cylindrical zone of diffuse secondary growth in ground and inner cortical tissues of the base and main trunk. Although similar to some monocots in general behaviour (23), secondary
growth in the stems of *Xinicaulis* did not produce distinctive radial files of parenchyma or additional vascular strands. Instead, continued activity served only to increase overall volume of the stem via mostly unordered parenchyma, and created patterned fracturing of the vascular strands at primary xylem dichotomies in both proximal and distal directions. Since increase in tissue volume has important consequences, both physiological and structural, it seems very likely that all cladoxylopsid plants of tree size using this mode of growth of necessity would have a hollow pith (Figs 3b, S1b). In addition, *Xinicaulis* is also associated with an equally unusual form of secondary development in which radial files of secondary xylem are produced by cambia around individual cauline strands, medullary strands and roots rather than forming a single solid cylinder as generally expected in seed plants. Secondary xylem greatly increased both conductive capacity and support presumably to keep pace with increasing size of the plant during development. It is interesting to note that cell walls of the secondary xylem in *Xinicaulis* are unusually thick, for example when compared with *Callixylon* (the trunk of the progymnosperm tree *Archaeopteris*) from the same locality (Fig. S7), possibly indicating relatively greater importance of support over conductive capacity in a fibrous plant body overall (and suggesting a significant capacity for cladoxylopsids to draw down atmospheric carbon).

The manner of secondary development in *Xinicaulis* seems potentially indeterminate and thus capable of producing trees of very large size. This invites close comparison with *Eospermatopteris*, with stumps showing similar size and taper as our largest Chinese specimen, and with a similar construction of the xylem system including longitudinal cauline xylem strands, anastomosing medullary xylem strands, central pith, and external adventitious roots (12, 13, 14). Fragmentary coalified, but clearly formerly woody, xylem strands have also been found preserved within *Eospermatopteris* casts (Fig. 1). However, unlike in the large Xinjiang
*Xinicaulis* specimen, the very bottom of the trunk is clearly represented. Our observations of *Eospermatopteris* suggest the initially upright, upwards-dichotomising, upwards-expanding part of the vascular system produced during early development may end up as a radially-expanded horizontally almost flattened disc (Fig. 1d) in larger trees due to continued lateral diffuse secondary growth combined with longitudinal structural failure with increasing size over time (Fig. 7).

By contrast, other cladoxylopsid trees such as *Pietzschia* so far exhibit only primary growth and retain an intact, partially vascularised pith (10, 11). If representative of determinate development, it seems likely that these examples adopted a tree fern strategy (18) whereby upwards-increasing complexity and size of the primary body (epidogenesis) was supported by an ever-enlarging root mantle. However, given what we know at this point in time, there is no reason to preclude intermediate conditions with various degrees of secondary development and concomitant shift in support strategy.

Most intriguing, perhaps, is the obvious convergence in form and development between *Xinicaulis*, and by implication some other cladoxylopsids, and living tree-form monocot angiosperms, such as palms, to be contrasted with ‘true’ secondary development via a single well-organised vascular cambium as seen in most lignophytes. Although unique in significant respects (production of secondary xylem around each vascular strand via a normal vascular cambium and patterned fracture of the primary xylem architecture during secondary development), the general mode of development of *Xinicaulis* is nevertheless eminently recognisable among modern forms. The model of both primary and secondary development in cladoxylopsids we propose closely follows a long-standing view by Eckhardt (p. 390 in ref. 19) so much so that nothing *ad hoc* seems necessary. Although strikingly similar, it is also
reasonably clear that cladoxylopsids and palms evolved these features independently (7), so
analogy in growth can only be carried so far. However, the fact that palms, *Xinicaulis*, likely
*Eospermatopteris* and, for that matter at least some cormose tree lycopsids, all share significant
structural similarities including few apical meristems, a strong central axis and many roots (or
for the last, usually termed “rootlets”) of nearly equal size, may indicate what is possible, but
perhaps also limiting, in plants of tree size lacking a standard single cylindrical vascular
cambium.

Methods

We predominantly studied thick transverse and longitudinal sections of the silicified trunks.
These were cut by saw and then polished by hand on a grinding wheel or on a vibrating lap to
give a uniform black finish. The exposed surfaces were etched for 45-90 seconds in hydrofluoric
acid (HF) in a dedicated HF fume hood. Testing of these samples showed that there was no need
to pre-treat the material in HCl in order to remove carbonates as none was present. The reaction
with HF resulted in the carbonised cell walls being clearly visible against the white frosted silica.
The sections were subsequently rinsed in water with the runoff neutralized in supersaturated
sodium carbonate solution. After neutralization, the specimens were further washed in running
water for several hours, and then air dried. Standard protocols and PPE for HF work were
adopted while handling HF and HF contaminated specimens. The dry specimens were
photographed with Nikon D800 camera and 60 mm macro lens, or Leica M12 microscope. Some
small thin sections were ground by hand using traditional techniques to study histological details.
They were photographed using Leica DMR compound microscope and Leica cameras.
Measurements were made using Leica LAS software.
ACKNOWLEDGEMENTS This study was financially supported by National Science Foundation of China (Grant Nos. 41530103, 41772012). NERC Grant NE/J007897/1 to C.M.B. with W.E.S. as visiting researcher made possible the collaboration between W.E.S, H.-H.X and C.M.B, and the parallel study of Eospermatopteris.

**a**, Distally-divided cauline primary xylem strand.  
**b**, Series through the dichotomy of cauline strand 12 with secondary growth (Fig. S5).  
**c**, Interpretation of **b** (above) showing pulling apart of the daughter xylem strands has caused a crack to be propagated basipetally. Development and proliferation of secondary xylem has kept pace with the splitting at the level of the cambium, but an area of parenchyma has developed under relative tension within the space delimited by the primary and secondary xylem.  
**d-f**, Developmental history of transverse section of xylem strand at level indicated by arrow in a-c (above).  
**d**, primary xylem only.  
**e**, one growth increment of secondary xylem. Secondary xylem and vascular cambium has proliferated.  
**f**, Further separation, parenchyma cells developing in gap between the separating halves of the strand show elongation under relative tension in the orientation indicated by double-headed arrow. Black = primary xylem, light grey =secondary xylem. Thick black line = vascular cambium. Dashed line = growth increment. White area = parenchyma.  
**g**, Series between interconnected medullary strands (blue) and cauline strand 20. Brown = adventitious root. Series drawn from slices A6-A8 (Fig. S6); suffix r means bottom of slice, drawing reversed. Thickness of slices approximately 8 mm, the distance between facing slabs (e.g. A6r to A7) is about 3 mm allowing for saw cut, grinding and etching. Outer medullary trace shows departure from the cauline strand (A8) and its distal connection with another inner medullary strand (A7). The series shows that the medullary strands are splitting apart acropetally as the inner medullary strand is ‘pulled’ towards the pith, evidenced by the formation and elongation (arrows) of parenchyma in the gap between the separating strands. The strand continues to split acropetally along a tangentially oriented crack (sections A7-A6r, dashed white line).

Fig. 7. *Xinicaulis lignescens* gen. et sp. nov. Schematic model of development showing the position of the blocks describe in this paper. A developmental model showing three growth stages of the trunk, in lateral (upper) and basal (lower) view. Colours show primary cauline xylem strands formed in a time series from the growing apex.  

**a**, Juvenile stage: the primary body has grown sufficiently to produce about 30 cauline strands by upwards dichotomy of individual
strands. b, Intermediate stage with further enlargement of the primary body, and a maximum number of cauline xylem strands produced (black lines). c, Mature stage with maximum secondary growth of cauline xylem strands to produce large diameter trunk. In this model we follow an unpublished hypothesis by Berry and Stein (to be elaborated elsewhere), based on observations on *Eospermatopteris* from New York, whereby the upwards-dichotomising cauline and medullary xylem system is gradually incorporated into the almost flat expanding base (Fig. 1d). The alternative, a tree-fern like basal system, as found in *Pietzschia* with primary growth only (ref. 18), is considered unlikely in such a large trunk. *Sp* shows the hypothetical position of the small trunk specimen with largely only primary growth, and *Ss* shows the position of the same specimen with secondary growth as illustrated in this paper. *Lp* shows the hypothetical position of the large trunk specimen with largely only primary growth, and *Ls* shows the position of the large specimen following secondary growth as illustrated in this paper.
