Keywords: Renewable fuels Molybdenum carbide Hydropyrolysis Hydrodeoxygenation Py-GC/MS

ABSTRACT

Fast hydropyrolysis of lignocellulosic biomass was studied by using an analytical pyrolyzer coupled with a gas chromatography/mass spectrometry set-up (Py-GC/MS). Under pure H2 stream, Canadian pine wood was rapidly heated up to 500 °C and the generated vapors passed through a catalytic bed at 500 °C. Experiments were carried out in order to compare the catalytic performance of MoC/Al2O3 catalyst to a reference catalyst based on noble metal (1.5 wt.% Pt/Al2O3). The effect of different supports (Al2O3, ZrO2 and MgO) on the carbide performance and product formation was investigated. The results showed that the performance of MoC/Al2O3 was similar to that of 1.5 wt.% Pt/Al2O3. Both of them deoxygenated the hydropyrolysis vapors and led exclusively to hydrocarbons formation. However, the proportion of aliphatic and aromatic hydrocarbons was different: MoC/Al2O3 catalyst produced more aliphatics (57%) than the Pt catalyst. The supports have demonstrated influence on the product distribution. Acidity of the support seems to play an important role in the deoxygenation of the vapors. While there was complete removal of oxygen when MoC/Al2O3 and MoC/ZrO2 were used, the same did not take place for the more basic MoC/MgO catalyst.

1. Introduction

It is a well-known fact that the intensive use of fossil fuels in the last decades has brought about economic, political and environmental concerns. In this way, great technological development efforts are being devoted toward their partial replacement by renewable and economically sustainable energy sources. Considering this, biomass appears as an alternative for producing fuels and chemicals once it has been valorized [1,2]. Bio-oil is a complex mixture of oxygenated organic molecules with undesirable properties such as low energy content, acidity, high viscosity and chemical instability. For instance, the presence of carboxylic acids and carbonyl compounds (aldehydes and ketones) leads to a corrosive nature and instability of the oil, respectively. Thus, the direct application of bio-oil as fuel shows several restrictions [3].

The upgrading of bio-oil can be achieved by reducing its oxygen content via deoxygenation reactions such as decarbonylation, decarboxylation, direct deoxygenation (hydrogenolysis), dealkylation, cracking, hydrocracking, hydrogenation, dealkylation, methyl transfer and hydrodeoxygenation reactions. Amongst them, the last one is the preferred route in the upgrading process once the oxygen is removed as H2O resulting in enhancement of liquid yields and no loss of carbon [5].

In order to promote bio-oil hydrodeoxygenation (HDO), many stu-dies found in the literature make use of traditional hydrotreating cat-ayls based on sulfides, temperatures around 300–500 °C and an ex-ternal source of hydrogen [5,6]. The use of sulfides must be avoided because some sulfur can be leached from the active phase and react with the molecules in the feed thus ending up in the final product, which is undesirable. Moreover, sulfur leaching leads to catalyst de-activation. Although noble metal catalysts can be also applied in...
The use of precious metals increases the final production costs [8]. A cheaper alternative is their replacement by transition metal carbides, which have catalytic behavior comparable to noble metal catalysts and are sulfur resistant [9].

Most of the works adopting transition metal carbides for biomass upgrading make use of model compounds as reactant in order to un-derstand the chemical steps involved in the mechanism of deoxygenation [5,10–18]. There are few studies using carbides in the upgrading of raw bio-oil. In one of them, Patel et al. [19] have investigated the fast pyrolysis of sugarcane bagasse in a fluidized bed reactor utilizing 20 wt.

% Mo2C/Al2O3 as catalyst. The authors have observed the reduction of sugars while the amounts of furanic and phenolic compounds have increased. However, no deoxygenation products were detected prob-ably due to the utilization of nitrogen as the fluidizing agent instead of hydrogen. In another study, Choi et al. [20] evaluated a series of metal-doped bulk Mo carbide in the hydropyrolysis of pine-derived bio-oil. Results showed that the presence of catalysts promoted the formation of hydrocarbons and the removal of oxygenated compounds, reaching an oxygen content reduction of 94% for the Ni-doped bulk Mo2C catalyst. Remarkably, this bulk carbide catalyst could be easily regenerated after deactivation. Nonetheless, the problem of the use of pyrolysis oil as a reactant for upgrading is the presence of reactive molecules easily regenerated after deactivation. Nonetheless, the pr-

otal process involves the presence of reactive molecules in the bio-oil that can in parallel undergo polymerization and increase the average molecular weight, which causes lower reactivity for hydrodeoxygenation [7].

Usually, fast pyrolysis of the biomass takes place in an inert atmo-sphere (N2, Ar or He). However, the thermal decomposition in the presence of H2 can allow the reaction between the volatile organic products and hydrogen. Although, literature reports that the use of H2 in a fast pyrolysis system does not lead to an extensive deoxygenation degree at low pressures, the addition of catalysts to the upgrading process has shown promise. The association between fast pyrolysis carried out in a reducing atmosphere and catalytic upgrading of pyr-olysis vapors leads to the concept of catalytic fast hydropro-

pyrolysis [21].

The main objective of this work was to evaluate the performance of supported molybdenum carbide catalysts in the deoxygenation of hydro-

pyrolysis vapors of pinewood using a pyrolyzer-gas chromato-

graphy/mass spectrometry (Py-GC/MS) system. Three different oxides (Al2O3, ZrO2 and MgO) were used as supports for molybdenum carbide in order to verify their effect on the overall distribution of the GC-vo-latil products. These materials were chosen due to their distinct acid-base properties.

2. Materials and methods

2.1. Catalyst preparation

γ-Al2O3 (Alfa Aesar 43832), ZrO2 (Gimex Technisch Keramik B.V. RC100) and MgO (Merck 105867) were used as supports for molybenum carbide. The precursors were synthesized by incipient wetness impregnation method using an aqueous solution of ammonia heptamolybdate ((NH4)6Mo7O24·4H2O, Sigma Aldrich) in order to ob-tain a carbide loading of 20 wt.%, followed by calcination at 500 °C (heating rate of 5 °C min⁻¹) for 5 h. The synthesized precursors 26 wt.

% MoO3/X (X = Al2O3, ZrO2 or MgO) were then carburized by means of temperature-programmed carburization (TPC) method. 100 mg of each sample was heated from room temperature up to 650 °C (heating rate of 2.5 °C min⁻¹) under a stream of 20 vol.% CH4/H2 (100 mL min⁻¹). The temperature was kept isothermal at 650 °C for 2 h before cooling down to room temperature. The use of these conditions allows the production of “clean” Mo2C, i.e. Mo2C without any carbon contamination due to thermal decomposition of methane as shown in literature [22,23]. As transition metal carbides are pyrophoric, an ad-ditional step of passivation was needed in order to avoid bulk oxidation after their exposure to the atmosphere. Therefore, all samples were passivated under a stream of 1 vol.% O2/N2 (30 mL min⁻¹) overnight.

For comparison purposes, a platinum catalyst supported on γ-Al2O3 (1.5 wt. % Pt/Al2O3) was prepared as described elsewhere [24].

2.2. Catalyst characterizations

Mo2O3 loadings were determined by using X-ray fluorescence tech-nique (XRF; Philips, PW1480). X-ray diffraction (XRD) patterns were recorded on a Rigaku Rix 3100 instrument with a Cu Kα radiation at 30 kV and 15 mA. The analyses were carried out in the 2θ range from 5 to 90° at speed of 2° per minute.

CO uptake measurements were carried out in situ immediately after TPC method by pulsing calibrated volumes of a 20 vol.% CO/He gas mixture at room temperature and acquiring online the ion signal m/z = 28 with a mass spectrometry (Pfeiffer Vacuum, model D-35614 Asslar).

The specific surface area values were obtained by N2 physisorption at ~196 °C. The values were calculated by B.E.T. method using a single point (P/Ph = 0.3). The analyses were carried out in situ and a complete description of the experimental procedure can be found in reference [25].

The total acid sites of reactivated carbide catalysts and pure sup-portes were quantified by adsorption of a 4 vol. % NH3/He gas mixture at room temperature. Prior to the experiment, the passivated carbide was reactivated in situ at 500 °C (heating rate of 10 °C min⁻¹) under a flow of pure H2 during 60 min. The ion signals m/z = 17 and m/z = 15 were monitored online by means of a mass spectrometry (Pfeiffer Vacuum, model D-35614 Asslar). The experimental procedure to determine the total quantity of chemisorbed NH3 matter was based on a dynamic method described in the Supplementary information.

2.3. Hydropyrolysis reaction

Fast hydropyrolysis experiments were carried out in a Pyroprobe® 5200 pyrolyzer (CDS Analytical) at atmospheric pressure. Approximately, 500 µg of biomass (Canadian pinewood) was loaded in a quartz tube reactor that was heated up to 500 °C at a heating rate of 20 °C ms⁻¹ under a flow of pure H2 (15 mL min⁻¹). The pyrolysis va-pors exiting the reactor passed through a catalytic fixed-bed reactor (3 mg of catalyst mixed with 3 mg of quartz sand) kept at 500 °C. All of the products were analyzed by an on-line GC/MS (Agilent, model 6890N-5975) equipped with a capillary column (Agilent VF–

1701 ms, 60 m length, 0.25 mm i.d., 0.25 µm film). Helium was used as carrier gas at a flow rate of 1.2 mL min⁻¹. The analyses were done using the following temperature profile: 40 °C for 5 min, raised up to 280 °C at 3 °C min⁻¹, held at 280 °C for 10 min. The mass spectrum of all de-tected products was obtained at 70 eV (ionization energy) using the scan mode (from m/z = 25 to m/z = 550). The identification of compounds was based on the obtained mass fragmentation patterns ac-quired by the coupled mass spectrometer using peak matching of cor-responding chromatographic peaks with those of NIST database.

Before hydropyrolysis, passivated carbides were reactivated (and Pt/Al2O3 catalyst was reduced) in situ at 500 °C under pure H2 stream for 30 min. Besides, the bulk MoO3 precursor was also tested and it was pretreated in situ at 500 °C under pure He stream for 30 min.

Each reaction was performed at least three times to check experi-mental reproducibility and calculate the confidence interval, con-sidering a confidence level of 95%.

As it is known, the use of Py-GC/MS system does not provide a fully quantitative analysis with high accuracy due to the complex nature of the bio-oil and the lack of commercial standards. However, many re-searchers have already proposed to apply a semi-quantitative analysis using the peak area percentage [26–30]. This relies on the fact that variations in the chromatographic peak area of a component are con-sidered linear with the variations of its quantity. Accordingly, varia-tions in the peak area percentage of this component is linear with the
Fig. 1. XRD patterns of bulk MoO₃ (a) and bulk Mo₂C (b). The crosses and circles re-present the characteristic diffraction peaks of MoO₃ (JCPDS 05-0508) and Mo₂C (JCPDS 35-0787), respectively.

variations of its concentration. Considering that all experiments were carried out using the same type and mass of feedstock, the comparison of the peak area percentages are significant.

The compounds identified by GC/MS were grouped as acids, car-bonyls, furans, phenols, aliphatic hydrocarbons (HC), aromatic HC, alcohols and miscellaneous (misc.).

3. Results and discussion

3.1. Catalyst characterizations

The XRD patterns of bulk MoO₃ and bulk Mo₂C synthesized by TPC are shown in Fig. 1(a-b). According to Joint Committee on Powder Diffraction Standards (JCPDS) database, both samples presented their characteristic diffraction patterns. MoO₃ exhibited the main diffraction peak at 2θ = 27.4°, corresponding to the (0 4 0) plane of an orthorhombic unit cell (JCPDS 05-0508). For bulk Mo₂C, the position of the highest relative intensity was at 2θ = 39.4°, ascribed to the (0 1 0) plane of a hexagonal close packed unit cell (β-Mo₂C crystalline phase) (JCPDS 35-0787).

Theoretically, to achieve a Mo₂C loading of 20 wt.% in a supported catalyst, the precursor should have a MoO₃ loading of 26 wt.% Considering the theoretical and real results obtained from XRF pre-sented in Table 1, it is possible to conclude that the catalyst synthesis was performed in a proper way, once the real loadings are close to the nominal ones for all of the synthesized samples.

Independently of the support, the high loadings of molybdenum oxide led to the formation of crystallites observable by XRD, as can be seen in Fig. 2(a). However, after the carburization step, it was not possible to identify any of the diffraction lines related to β-Mo₂C (vertical dotted line in Fig. 2(b)). Only the diffraction peaks of the supports (γ-Al₂O₃ at 2θ = 36.8°, 45.5° and 66.5°; monoclinic ZrO₂ at 2θ = 24.2°, 28.2°, 31.5°, 34.2°, 35.3°, 40.7° and 50.1°; cubic MgO at 2θ = 36.8°, 42.8°, 62.2°, 74.5° and 78.4°) were identified, as can be seen in Fig. 2(b). Thus, the absence of characteristic diffraction peaks of β-Mo₂C in the supported samples might indicate the formation of very small particles highly dispersed and presenting crystallite sizes below the detection limit. In fact, HRTEM micrographs presented in the Supplementary Information (please see Figs. S2, S3 and S4) show that the observed particles have sizes in the range from 1 to 5 nm after the carburization step.

Despite the fact that was not possible to pinpoint the exact nature of the formed phase after the carburization step, a proof that the original molybdenum oxide species were transformed into carburized species (hereafter referred as MoC/X, X = Al₂O₃, ZrO₂ or MgO) is given by the CO uptake results presented in Table 2, where neither the oxidic sam-ples nor the support chemisorb this probe molecule.

The specific surface area (S²) values of the supports (X = Al₂O₃, ZrO₂ and MgO), precursors (26 wt.% MoO₃/X) and catalysts (bulk Mo₂C and MoC/X) are presented in Table 2. It can be observed that the specific areas of the MoO₃/X samples were lower than those of the corresponding supports, as expected. It is known that bulk MoO₃ has a low specific area (S² < 0.2 m² g⁻¹) [31]. Therefore, the decrease in the S² value was coherent with the MoO₃ content, corresponding to 26% of the support total area. After the carburization, the supported carbides showed an increase of the specific area value if compared to their precursors. Bulk Mo₂C presents a considerably higher value compared to that of bulk MoO₃.

From the ammonia uptake showed in Table 2, it is possible to conclude that the acidity of the supports follows the order MgO < ZrO₂ < Al₂O₃, which is in agreement with the literature [32]. Bulk Mo₂C presents a significant NH₃ uptake (58 µmol g⁻¹), in accordance to the previous re-sults demonstrated by Bej et al. [33]. It is noteworthy that MoC/Al₂O₃ catalyst presents more acid sites (250 µmol of NH₃ g⁻¹) than the sum of the individual contributions of MoC (0.2 × 58 = 11.6 µmol of NH₃ g⁻¹) and Al₂O₃ (0.8 × 136 = 108.8 µmol of NH₃ g⁻¹). This result can be ex-plained considering that while bulk MoC presents big particles, when supported the carbonate is in a highly-dispersed form, which leads to the formation of more acid sites.

3.2. Hydropyrolysis of biomass

The hydropyrolysis of Canadian pinewood was carried out in a Py-GC/MS set-up which can only be conducted in batch mode. It is im-portant to highlight that this type of system shows some drawbacks that should be addressed. The main one concerns the reaction products which cannot be collected due to the extremely low quantity (~500 µg) of the feedstock employed in the experiments. For this reason, it is not possible to obtain the mass balance and to monitor the gas phase. However, a previous report in the literature [34] has proven that the composition of volatile pyrolysis products obtained from Py-GC/MS and a bench-scale pyrolyzer is in close agreement. This result reveals that Py-GC/MS can be successfully used as a qualitative technique to screen catalysts and to indicate the nature of the formed products.

The first set of experiments consisted to perform the thermal hydropyrolysis without catalyst, in order to evaluate the organic mole-cules which will be catalytically upgraded later. In this experiment, more than 100 compounds were detected by GC/MS, as can be ob-served in a typical chromatogram showed in Fig. S5 (Supplementary information). It is noteworthy that this analysis method only captures the volatile products. However, it is important to be aware that there is also the formation of biochar, lights gases and a portion of tar which were not analyzed in this work.

Due to the large number of products obtained during the thermal experiment, Table 3 lists only the compounds with chromatographic peak area percentages higher than 1%. A variety of oxygenated com-pounds were produced including simple molecules (such as carboxylic acids, ketones, aldehydes, alcohols and esters), furans and sugars, which come from the decomposition of cellulose and hemicellulose, as well as phenolic compounds derived from lignin (such as phenols, cresols and guaiacols). Acetic acid has shown the largest peak area percentage suggesting that this was the major product from the reac-tion. Its formation can take place by different routes, being the

deacetylation of hemicellulose the most likely one [26]. Regarding the phenolic compounds, it is well-known that lignin can undergo demethoxylation, demethylation and alkylation reactions. Demethoxylation reactions can form compounds such as phenol, guaiacol and 4-ethylphenol, whereas demethylation and alkylation reactions can pro-duce catechol and o cresol, respectively [26].

In order to deoxygenate the organic volatile molecules formed during thermal hydrolysis, a set of catalyst samples were tested one-by-one. Regarding to the upgrading experiments, it is relevant to emphasize the importance of biomass-to-catalyst ratio on the product distribution. It is reported in the literature [30,35,36] that low ratios (< 0.2) lead to high deoxygenation extent. On the other hand, ratios higher than 0.3 favor oxygenated compounds formation, such as carboxylic acids, furans, phenols and cresols. Taking into consideration that this work aimed at forming compounds with low oxygen content, all experiments were undertaken at a biomass-to-catalyst ratio of 0.17, in order to perform an efficient deoxygenation and maximize the for-mation of hydrocarbons.

Fig. 3 compares the product distribution of thermal experiment with the results achieved by using bulk MoC and its respective oxide, as well is also observed in Table 4. As can be seen, the non-catalytic hydro-pyrolysis led to generation of high amounts of oxygenates including 9% of acids, 38% of carbonyl containing compounds, 12% of furans and 28% of phenols. When MoO3 was used as catalyst in the hydrolysis reaction, there was a complete suppression of the phenolic compounds with the corresponding formation of aromatic hydrocarbons. This result is in agreement with those reported by Prasomsri et al. [37] for the hydrolysis of lignin-derived model compounds using MoO3 as catalyst. The authors propose that during the hydrolysis reaction MoO3 undergoes a partial carburization forming oxy-carbide- and/or oxy-carbo-hydride-containing phases that would be responsible for the catalytic activity. However, the hypothesis that the deoxygenation takes place on oxygen vacancies created on MoO3 through a reverse Mars-Van Krevelen reaction cannot be ruled out [38]. It is noteworthy...
that the amounts of acids, carbonyls and furans have remained broadly unchanged when compared with the thermal hydrolysis indicating that under the reaction conditions employed deoxygenation of phenols takes place preferentially.

Prasomsri et al. [37] have found that when treated in hydrogen flow at 400 °C, MoO3 is active in the HDO of several oxygenated molecules (e.g., acetone, phenol, 2-hexanone, anisol, 2-methylfuran and 2,5-di-methylfuran) due to the oxygen vacancies formation. Our results show that only phenolic compounds were converted when MoO3 was used as catalyst and the explanation for this can be related to the fact that in our case, the oxide was submitted to a thermal treatment under flow of He at 500 °C. In this way, the vacancies created in the MoO3 lattice would occur only during the reaction when hydrogen is present in the feed.

Significantly, the use of bulk MoO3 as catalyst (Fig. 3) led to for-mation of hydrocarbons (aliphatics and aromatics) with no formation of other oxygenates such as acids, carbonyls, furans and phenols. This result indicates that MoC was able to transform oxygenated com-ounds into aromatic and aliphatic hydrocarbons, showing an extensive hydro-deoxygenation degree, as previously demonstrated for HDO re-actions employing model molecules such as acetone [10, 18], propanal [18], acetic acid [39], benzofuran [40] and a phenolic compound

mixture (guaiacol, anisole, m-cresol, 1,2-dimethoxybenzene) [41]. Be-cause of the small amounts of catalyst used in the hydropyrolysis ex-periments, it was not possible to study the catalyst after the reaction to check out if part of the oxygenated compounds were transformed into coke.

As mentioned earlier, it is well known from the literature that car-bide catalysts have catalytic behavior similar to that of noble metal catalysts [9]. Thus, the 1.5 wt.% Pt/Al2O3 catalyst (characterization available in the Supplementary Information) was tested, in order to compare its product distribution to that of MoC/Al2O3 catalyst. The hydropyrolysis experiments were carried out under the same conditions and the results are presented in Fig. 4. The use of pure Al2O3 led to a suppression of the acids and phenols, 70% of carbonyls were converted and, interestingly, 77% of hydrocarbons were formed. This might be due to the dehydration of acids and phenols over the acid sites of Al2O3 [3]. Over Pt/Al2O3 catalyst, all the oxygenates were converted into aliphatic (42%) and aromatic (58%) HC. Promisingly, MoC/Al2O3 cat-alyist only produced aliphatic and aromatic hydrocarbons (57% and 43%, respectively), as well. Both Pt and MoC catalysts have the ability of complete deoxygenation and production of aliphatics, especially. In comparison, earlier report by Bridgewater [42] showed that total deoxygenation could be achieved over ZSM-5 but only (poly) aromatics were formed.

Comparatively, Pt/Al2O3 catalyst favored aromatic HC formation while MoC/Al2O3 catalyst promoted aliphatic formation. The difference in the amount of aromatics formed on Pt and MoC catalysts might be related to the acid sites of Al2O3, over which aromatization takes place [3]. As the loading of the active phases are quite different, it is rea-sonable to assume that alumina coverage was higher in the supported carbided catalyst, thus resulting on less acid sites from the Al2O3. The compounds produced over Pt/Al2O3 and MoC/Al2O3 catalysts are dis-played in Fig. 5 and it is noteworthy that the major aromatic com-pounds over Pt/Al2O3 catalyst were benzene and toluene, and the al-iphatic HC were C4 compounds (25 %). However, over MoC/Al2O3 catalyst, a variety of other aromatic compounds with one ring (26%) were produced, such as ethylbenzene and xylene, and 37% of aliphatic HC corresponded to C5-C9 compounds which are the most compatible fuel components. Besides, both of them produced approximate amounts of compounds consisting of 2 aromatic rings, such as naphthalene and fluorene. As it is known, Al2O3 favors the polymerization reaction and coke formation, thus this result is in accordance with the literature [43].

The results presented in Figs. 4 and 5 clearly show that the MoC/Al2O3 catalyst exhibited high reactivity for upgrading of hydropyrolysis vapors. In order to investigate the effect of the acidity of the support over molybdenum carbide active phase performance in the hydro-pyrolysis of biomass, other supports were employed.

Figs. 4, 6 and 7 show that the acid-base properties of supports strongly influence the product distribution obtained during hydro-pyrolysis using carbide as active phase. In general, the acidity favored the production of aliphatic and aromatic hydrocarbons via dehydration reactions [3] and reduction of carbonyls compounds. On the other hand, the basic feature favored CeC coupling reactions (e.g. aldol-condensation, ketonization), which leads to the increasing of molecular chain, but not the removal of oxygen atom [44]. It is clearly observed that Al2O3, being the most acidic support, produced the highest per-centage of total HC (77%) and the lowest percentage of carbonyls (12%), while MgO, being the basic (less acidic) support, presented the opposite behavior (18% of total HC and 70% of carbonyls). As expected, the ZrO2 support showed intermediate percentages of total hydro-carbons (52%) and carbonyls (40%), as it is an amphoterich material.

As can be seen in Table 4, hydrocarbon and carbonyl groups were produced by all supports, as well as furanic compounds, being furan the component present in the largest amount. Furthermore, phenolic spe-cies were also formed, but not in an appreciable quantity. Comparing with the thermal hydropyrolysis, it is noted that Al2O3, ZrO2 and MgO reduced all the guaiacol derivatives, remaining only the phenolic ones such as phenol, 2-methyl phenol and 2,6-dimethyl phenol.

The incorporation of carbide to the supports promoted the pro-duction of more hydrocarbons than what was obtained for the bare

Fig. 4. Product distribution obtained in the biomass thermal hydropyrolysis and catalytic hydropyrolysis using Al2O3, 1.5 wt.% Pt/Al2O3 and MoC/Al2O3 as catalysts.

Fig. 5. Compounds produced during biomass catalytic hydropyrolysis using 1.5 wt.% Pt/Al2O3 and MoC/Al2O3 as catalysts.

Fig. 5. Product distribution obtained in the biomass thermal hydropyrolysis and catalytic hydropyrolysis using ZrO2 and MoC/ZrO2 as catalysts.
supports, indicating that MoC was active in hydrodeoxygenation. Comparatively, it is observed that MoC/Al2O3 and MoC/ZrO2 catalysts led to a complete deoxygenation of the hydropyrolysis vapors forming outputs with different compositions but consisting of hydrocarbons (60% and 40% of aromatics and aliphatics, respectively).

The MoC/ZrO2 catalyst favored the formation of benzene and toluene, corresponding to half of the total aromatic hydrocarbons formed. In contrast, these compounds represented only one quarter of the formed aromatics in MoC/Al2O3 catalyst. Amongst the aliphatic hy-drocarbons, MoC/ZrO2 catalyst led to a major formation of C3 com-ponents (propene and propane), corresponding to one third (20%) of the total aliphatic compounds, whereas MoC/Al2O3 catalyst promoted the production of C5–C9 compounds.

One would expect that the more acidic catalyst (MoC/Al2O3) would lead to the formation of cracking products. When Table 4 is analyzed, it is clear that MoC/ZrO2 showed the highest formation of C3 compounds (20.9%), whilst the most acidic catalyst (MoC/Al2O3) pre-sented a rather low formation of these kind of products (5.9%). This suggests that the formed C3 compounds observed for the MoC/ZrO2 catalyst were not only formed by cracking reactions, but also by hy-drogenation of acetone formed during the hydropyrolysis of pinewood (thermal experiment). Moreover, the acetate acid presented in the vapor can undergo ketonization reaction, leading to the formation of more acetone and ZrO2 was already reported as one of the best catalysts to perform this reaction [32]. Another important point to be considered is that on bare ZrO2 there is the formation of a high amount of acetone (19.9%), then it is reasonable to assume that this ketone formed on the support could be hydrogenated to propane on the MoC sites, thus explaining the high quantities of observed C3 products.

Analysis results presented in Fig. 7 reveals that not all oxygen was removed when MoC/MgO was used as catalyst. In this case, only 35% and 70% of the carbonyl and furan compounds were converted, re-spectively, although there was a complete conversion of acids, phenols and alcohols. The carbonyl compounds that remained were acetone (17%) and 2-butaneone (3.5%), whereas the furans were 2-methylfuran (2.2%) and 2,5-dimethylfuran (1.3%). Moreover, this catalyst produced 72% of hydrocarbons, 51% of aliphatic species, which is a lower value than those obtained for MoC/Al2O3 and MoC/ZrO2. Amongst the formed aliphatic HC, C5–C9 compounds appeared in major proportion (19%), whereas compounds with one aromatic ring, excluding benzene and toluene, were the most generated (11%) in the aromatic group.

The chemistry behind the reactions taking place during the thermal or catalytic pyrolysis reactions is quite complex and changes depending on the nature of the employed biomass. However, if the formed carbonyl compounds are grouped into families an explanation of the role of the carburized species can be attempted. For instance, several works in the literature have shown that molybdenum or tungsten carbide are used as catalysts in the hydroydeoxygenation of carboxylic acids [31,45–48] there is the hydrogenation of the carboxyl group, con-trarily to what is observed for noble metals, which promote dec-arbonylation and decarboxylation reactions. This behavior was ob-served in this work where the use of the molybdenum carbide has led to a suppression of the acids formed. However, in order to fully stand the role of the carbide active phase in the reaction networks in-volved and the interaction between the different families of compounds more fundamental studies using model molecules and mixtures of them are needed.

4. Conclusions

It is shown in this study that the MoC/Al2O3 catalyst showed high reactivity for upgrading of hydropyrolysis vapors, with its performance being comparable with 1.5 wt.% Pt/Al2O3. Thus, carbide-based catalyst is a promising alternative for the expensive (Pt) noble metal catalyst once they deoxygenated the pyrolysis vapors generated in the fast hy-dopyrolysis of Canadian pinewood to aliphatic and aromatic hydro-carbons, which are the most compatible fuel components. In addition, for the supported MoC catalysts, the acidity of the support influences the overall catalytic performance, leading to a larger formation of hy-drocarbons and to the deoxygenation of carbonyl compounds. Supported carbide catalysts studied here seem bifunctional. The sup-port have a definite role in the (inter)conversion of fragments formed during pyrolysis via catalyzing dehydration, coupling (de)-alkylation and condensation reactions. Thus, the product pattern, aliphatics vs aromatics, can be manipulated by the choice of the support. Carbide catalysts show a satisfactory catalytic performance and, undoubtedly, are a potential alternative to replace noble metal in the hydropyrolysis of biomass to liquid fuels.
