Abstract

We set out to determine the ratio, $q_{IR}$, of rest-frame 8–1000-µm flux, $S_{IR}$, to monochromatic radio flux, $S_{1.4 \text{GHz}}$, for galaxies selected at far-infrared (IR) and radio wavelengths, to search for signs that the ratio evolves with redshift, luminosity or dust temperature, $T_d$, and to identify any far-IR-bright outliers – useful laboratories for exploring why the far-IR/radio correlation (FIRRC) is generally so tight when the prevailing theory suggests variations are almost inevitable. We use flux-limited 250-µm and 1.4-GHz samples, obtained using Herschel and the Very Large Array (VLA) in GOODS-North (-N). We determine bolometric IR output using ten bands spanning $L_{bol} = 24–1250\ \mu\text{Jy}$, exploiting data from PACS and SPIRE (PEP, HerMES), as well as Spitzer, SCUBA, AzTEC and MAMBO. We also explore the properties of an L$_{IR}$-matched sample, designed to reveal evolution of $q_{IR}$ with redshift, spanning log $L_{IR} = 11–12\ L_{\odot}$ and $z = 0–2$, by stacking into the radio and far-IR images. For 1.4-GHz-selected galaxies in GOODS-N, we see tentative evidence of a break in the flux ratio, $q_{IR}$, at $L_{1.4 \text{GHz}} \sim 10^{22.7}\ \text{W Hz}^{-1}$, where active galactic nuclei (AGN) are starting to dominate the radio power density, and of weaker correlations with redshift and $T_d$. From our 250-µm-selected sample we identify a small number of far-IR-bright outliers, and see trends of $q_{IR}$ with $L_{1.4 \text{GHz}}$, $L_{IR}$, $T_d$ and redshift, noting that some of these are inter-related. For our $L_{IR}$-matched sample, there is no evidence that $q_{IR}$ changes significantly as we move back into the epoch of galaxy formation: we find $q_{IR} < (1+z)^{2.4}$, where $\gamma = -0.40 \pm 0.03$ at $z = 0–2$; however, discounting the least reliable data at $z < 0.5$ we find $\gamma = -0.26 \pm 0.07$, modest evolution which may be related to the radio background seen by ARCADE 2, perhaps driven by $<10^{-19}\text{Jy}$ radio activity amongst ordinary star-forming galaxies at $z > 1$.

Key words. galaxies: evolution – galaxies: starburst – infrared: galaxies – submillimeter: galaxies – radio continuum: galaxies

1. Introduction

For samples of local galaxies, and ~100-µJy scales, there is a good correlation between far-IR and radio emission (de Jong et al. 1985; Helou et al. 1985; Condon et al. 1991; Yun et al. 2001). The correlation spans many orders of magnitude in luminosity, gas surface density and photon, cosmic-ray and magnetic energy density, and arises because the far-IR and radio wavelength regimes share a common link with luminous, massive stars and their end products – dust, supernovae (SNe) and cosmic rays. In the simplest models (dubbed “calorimetry” – e.g. Voelk 1989; Lisenfeld et al. 1996), dust absorbs all of the ultraviolet radiation from massive stars, re-radiating this energy in the far-IR, and when those massive stars explode as SNe they generate cosmic-ray electrons which lose all their energy in the radio regime, mainly via synchrotron emission. A balance is thereby achieved between far-IR and radio emission, assuming that the starburst timescale is sufficiently long (>10$^7$ yr).

Traditionally, $L_{IR}$ and $L_{radio}$ are both employed to determine star-formation rates, and the far-IR/radio flux density ratio has been useful when estimating the redshift or $T_d$ of a distant starburst, or when defining samples of AGN (Condon 1992; Carilli & Yun 1999; Ivison et al. 2002; Bell 2003; Chapman et al. 2005; Donley et al. 2005), or probing magnetic field strength (Thompson et al. 2006). For these reasons, and because of recent observational advances at both far-IR and radio wavelengths, there has been a deluge of FIRRC-related work.

* Herschel is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA.
recently, exploring why the correlation exists and whether it continues to hold at progressively larger look-back times (Garrett 2002; Appleton et al. 2004; Ibar et al. 2008; Seymour et al. 2009; Ivison et al. 2010; Sargent et al. 2010a). Prevaling theory (e.g. Lacki et al. 2010) suggests that variations in the far-IR/radio flux ratio should be virtually unavoidable and that the FIRRC thus arises due to a mysterious combination of effects involving bremsstrahlung, inverse Compton cooling, ionisation and the relative fractions of primary/secondary cosmic-ray electrons/protons, as well as the critical synchrotron frequency.

Aside from the modelling work of Lacki et al., recent advances in this field have included the use of luminosity-matched samples (between high and low redshift) to better probe evolution with look-back time (Sargent et al. 2010b) and the use of measurements spanning the far-IR and radio wavebands to avoid assumptions relating to $k$ corrections (Ivison et al. 2010), although Calzetti et al. (2010) have argued that bands beyond 24 $\mu$m contain a contribution from dust heated by stars from previous episodes of star formation and so we might not necessarily expect the correlation to improve. In this paper we introduce flux-limited 250-$\mu$m- and 1.4-GHz-selected samples of galaxies from Herschel and the VLA, as well as a luminosity-matched sample selected at 24 $\mu$m, spanning $z = 0–2$, and determine their spectral energy distributions (SEDs) spanning the entire far-IR spectral region. We then investigate the FIRRC from the perspectives of the 24-, 250-$\mu$m- and radio-selected samples.

2. Sample selection and data analysis

In this paper we present results from observations with Herschel (Pilbratt et al. 2010). The SPIRE instrument, its in-orbit performance, and its scientific capabilities are described by Griffin et al. (2010), and the SPIRE: astronomical calibration methods and accuracy are outlined in Swinyard et al. (2010). PACS is described by Poglitsch et al. (2010).

Our datasets are drawn from the common area observed by PACS and SPIRE at 100, 160, 250, 350 and 500 $\mu$m as part of HersMES (Oliver et al., in prep.) and PEP (Lutz et al., in prep.) in the GOODS-N field, prior to acquisition of data for GOODS-Herschel. GOODS-N has also been observed with the VLA at 1.4 GHz (1.7" FWHM – Biggs & Ivison 2006; Morrison et al. 2010) and Spitzer at 24, 70 and 160 $\mu$m; we make use of these data, as well as the 850-, 1100- and 1250-$\mu$m images of Borys et al. (2003), Perera et al. (2008) and Greve et al. (2008).

We employ three GOODS-N galaxy samples, all selected above a signal-to-noise threshold of 5$\sigma$:

1. 128 galaxies selected at 250 $\mu$m, without priors, with $S_{250 \mu m} > 20$ mJy (Fig. 1; Smith et al., in prep.);
2. 247 galaxies selected at 1.4 GHz (Fig. 1) with a $S_{1.4 \text{ GHz}}$ limit of $\sim 20\mu$mJy, 137 with spectroscopic redshifts (Barger et al. 2008), the remainder with photometric redshifts ($\langle z \rangle = 0.94$; interquartile $z = 0.56$–1.76);
3. a $L_{IR}$-matched sample of 652 sources spanning $z = 0–2$, selected initially at 24 $\mu$m (Magnelli et al. 2009; Berta et al. 2010) then filtered to cover only the decade of $L_{IR}$ between $10^{11}$ $\rightarrow 10^{12} L_{\odot}$ (LIRGs), where $L_{IR}$ is determined using the models of Chary & Elbaz (2001).

Far-IR and submm flux densities for the three samples are determined using images convolved with appropriate point spread functions. $S_{\text{IR}}$ is calculated by integrating under the well-sampled SEDs. Monte-Carlo simulations are used to assess the uncertainty in $S_{\text{IR}}$. The formal error on $S_{25 \mu m}$ was boosted by 3$\times$ to account for the uncertain shape of the SED between rest-frame 8–70 $\mu$m. A modified blackbody fit to the measurements beyond 24 $\mu$m (with the emissivity index, $\beta = 1.5$) was used to determine $T_d$.

For sample (1), additional procedures are implemented to define a clean sample, free from blends: following the procedure of Downes et al. (1986), 107/128 sources are found to have secure ($P < 0.05$) radio identifications (ids) within a search radius, $r = 10''$; we discard the remainder. To avoid using those sources most severely affected by blending, we further discard those with more than one radio emitter within $r$, leaving 65 sources. Of the galaxies without a secure radio id, three have no plausible radio ids within $r$: a potentially interesting sub-sample. Measurements are made at the radio positions for the 65 sources with secure, unambiguous ids, and at the 250-$\mu$m positions for the three sources without radio emission.

For sample (2), far-IR and submm measurements are made at the radio positions.

For the $L_{IR}$-matched galaxies (sample 3), median stacking is used to measure $S_{\text{IR}}$ and $S_{1.4 \text{ GHz}}$; we follow the procedure outlined by Ivison et al. (2010). Fluxes are calculated from 31$^2$-pixel$^2$ stacked images in the ten available filters and $S_{\text{IR}}$ is determined as before.

3. Results and conclusions

$Q_{\text{IR}}$ as utilised here is the logarithmic ratio of the rest-frame 8–1000-$\mu$m flux, $S_{\text{IR}}$, and the 1.4-GHz flux density, $S_{1.4 \text{ GHz}}$, such that $Q_{\text{IR}} = \log_{10} [(S_{\text{IR}}/3.75 \times 10^{12} \text{ W m}^{-2})/(S_{1.4 \text{ GHz}}/\text{W m}^{-2} \text{Hz}^{-1})]$, where $S_{1.4 \text{ GHz}}$ is k-corrected assuming $S_{\nu} \propto \nu^{\alpha}$, with $\alpha = -0.8$.

We begin with sample (1), those selected at 250 $\mu$m: $Q_{\text{IR}}$ is not a strong function of $S_{\text{IR}}$ (Fig. 2), nor of $S_{1.4 \text{ GHz}}$. We see no evidence of contamination by radio-loud AGN, consistent with

Fig. 1. 250-$\mu$m image of GOODS-N, with $\geq 5\sigma$ 250-$\mu$m [radio] sources marked by circles [crosses]. The PACS region is also indicated. Here, $\sigma$ includes instrumental and confusion noise combined in quadrature, where $\sigma_{\text{conf}}/\sigma_{\text{nute}} \sim 5$ (cf. $\sim 2$ for BLAST).
the findings of Yun et al. (2001). Some galaxies stand out as potentially far-IR-bright: these include the three galaxies without plausible radio ids, two of which are detected at 70 and/or 160 µm, so are likely at low redshift with their radio emission resolved away. Only 39/65 sources with unambiguous radio ids have redshifts (20 photometric, 19 spectroscopic; ⟨z⟩ = 0.98; interquartile z = 0.46–1.52, similar to sample 2). Nevertheless, this sub-sample allows us to explore correlations between qIR and luminosity, redshift and Td. We find significant (>95% confidence – Table 1) trends for lower qIR amongst the most radio- and far-IR-luminous galaxies, and the warmest and most distant, though these parameters are likely inter-related. The dependence of qIR on L1.4 GHz is the strongest and likely reflects the influence of low-radio-power AGN, of which more later; that of qIR on LIR is more puzzling, perhaps reflecting the dependence of LIR on redshift and/or Td (e.g. Chapman et al. 2005), or selection effects (since this trend is not seen for sample 2 – see Table 1).

Figure 3 shows qIR versus redshift for our radio-selected galaxies (sample 2), split into five log-spaced bins of L1.4 GHz. Does qIR evolve with redshift? One might conclude that it does, based on the bottom panel of Fig. 3, where qIR ∝ (1 + z)γ, with γ = −0.05 ± 0.01 (Table 1). However, we must be aware of some strong selection effects which make this evidence unreliable: radio emission can be due to an AGN and several radio-loud objects with low values of qIR are obvious in Fig. 3. Such AGN are more common at z ∼ 2 than today (e.g. Wall et al. 2005); moreover, radio emission from faint starbursts (with α = −0.8, although see Ibar et al. 2010) becomes more difficult to detect at higher redshifts, such that the fraction of radio-loud AGN in a flux-limited sample will rise, driving down qIR. Indeed, Fig. 4 shows tentative evidence of a break in (qIR) at L1.4 GHz ∼ 10^{22.7} W Hz^{-1}. One might also expect radio-loud objects (those with low qIR) to contain warmer, AGN-heated dust, giving rise to the weak trend (89.2% confidence – Table 1) of decreasing qIR with increasing Td.

Finally, we turn to our LIR-matched galaxies (sample 3), illustrated in Fig. 5. The Δz = 0.5 bins provide significant numbers of objects at near-constant LIR spanning z = 0−2. As well as being matched in LIR, there is another key difference between our new sample and that used by Ivison et al. (2010): although

![Fig. 3. qIR versus redshift for our radio-selected galaxies (sample 2), in five bins of K-corrected L1.4 GHz, plus the full sample. Values of qIR for sample 3 are shown (as circles) for comparison.](image)
the new sample is based initially on a flux-limited 24-µm catalogue, the final selection is based on $L_{IR}$, with model-dependent extrapolations from the mid-IR (accurate to $\pm 2\times$ across all bins – Fig. 5). This should lead to less contamination by AGN at the blue end of the rest-frame 8–1000-µm band, where the relative contribution to $S_{IR}$ can be substantial (Fig. 11 – Ivison et al. 2010). Using our new sample, there is no strong evidence that $q_{IR}$ changes as we move back into the epoch of galaxy formation at $z \sim 2$, with $\gamma = -0.04 \pm 0.03$ where $q_{IR} \propto (1 + z)^{\gamma}$, consistent with the findings of Sargent et al. (2010b). If we discount the $z < 0.5$ data, which comprise only 16 galaxies which are not well matched in $L_{IR}$ to the higher redshift bins, we find $\gamma = -0.26 \pm 0.07$. This is similar to the $\gamma = -0.15 \pm 0.03$ found by Ivison et al. (2010) who noted reports that evolution in $q_{IR}$ could be related to the radio background seen by ARCADE2 (Fixsen et al. 2009; Seifert et al. 2010). Our sample, with $(S_{1.4\ GHz}) \leq 10$ mJy at $z > 1$, is consistent with the idea that evolution of the FIRRC might be driven by $<10$-mJy radio activity amongst ordinary star-forming galaxies at $z > 1$ (Singal et al. 2010).

Fig. 4. Median $q_{IR}$ versus $L_{1.4\ GHz}$. The local luminosity functions of starbursts and AGN are shown (Mauch & Sadler 2007).

Fig. 5. $L_{IR}$ (dots; left axis) and $q_{IR}$ (red circles; right axis) – the former determined via the models of Chary & Elbaz (2001) – versus redshift for our $L_{IR}$-matched sample. The luminosity bounds and redshift bins (dashed lines), the number of galaxies in each bin and their predicted (measured) ($\log L_{IR}$) and measured ($q_{IR}$) are all shown. The shaded area represents a $\pm 1\sigma$ prediction for $q_{IR}$ (Swinbank et al. 2008; Ivison et al. 2010).
