## Abstract

This paper investigates the potential for a causal relationship between certain supply-side policies and UK output and productivity growth between 1970 and 2009. We outline an open economy DSGE model of the UK in which productivity growth is determined by the tax and regulatory environment faced by firms. This model is estimated and tested using simulation-based econometric methods (indirect inference). Using Monte Carlo methods we investigate the power of the test as we apply it, allowing the construction of uncertainty bounds for the structural parameter estimates and hence for the quantitative implications of policy reform in the estimated model. We also test and confirm the model's identification, thus ensuring that the direction of causality is unambiguously from policy to productivity. The results offer robust empirical evidence that temporary changes in policies underpinning the business environment can have sizeable effects on economic growth over the medium term.

## 1 Introduction

In this study, simulation-based econometric methods are used to investigate whether certain supply-side policies – specifically tax and regulatory policies – affected economic growth in recent UK history (1970-2009). This period saw major reform to

the UK's institutions: marginal tax rates were reduced and the regulative system was altered, notably including hiring and firing restrictions and union laws. The stated objective of these so-called 'supply-side' reforms was to reduce barriers to entrepreneurial innovation and so affect the macroeconomy via the production function. The episode has attracted great interest from academics and policymakers alike as a case study of what supply-side policy can or cannot achieve, and continues to do so. The UK government's Plan for Growth (HM Treasury 2011) emphasized the business start-up and operation channel, to be targeted by reducing "burdens" from tax and regulation, in particular employment regulation.<sup>1</sup> No UK government since has signalled a movement away from this strategy; alongside its protective role, regulatory policy is viewed as a barrier to entrepreneurship and hence to growth.<sup>2</sup> The area has become heavily politicised, but there are empirical questions here which deserve examination and this is what we set out to do in this paper.

We take a DSGE model of the (highly open) UK economy in which supply-side policy affects incentives to set up innovative business ventures at the microfoundational level, and so plays a causal role in aggregate productivity behaviour over the short- to medium-run. The model is estimated and tested using Indirect Inference methods (Le et al. 2011). Two recent surveys of this testing method published in this journal (Le et al. 2016; Meenagh et al. 2019) set out how its power exceeds the traditional data-likelihood method. It also has low estimation bias in small samples. In this paper, we present the results of our own Monte Carlo exercise into the power of this test as we have applied it. We also apply a test of identification (Le et al. 2017) to the DSGE model, complete with its unambiguous relationship from policy to productivity growth, finding that it is indeed identified. With this assured, the result of the Indirect Inference test offers empirical support (or a lack of it, should the model be rejected) for the specified growth policy mechanism. Furthermore, the results of the power exercise imply uncertainty bounds for the structural parameter estimates we obtain and for the quantitative results of policy reform exercises conducted with the estimated model. The work is therefore complementary to existing empirical work on the macroeconomic effects of structural reforms, as there is no question about the exogeneity of policy in the identified model, and the conclusions rest on an estimated structural model that is formally evaluated by classical econometric methods.

We find that this model in which temporary supply-side policy shocks generate long-lasting productivity growth episodes is not rejected for the UK 1970-2009 sample with the estimated parameter set. Using the estimated model, a one-off 1

<sup>1</sup>The "overarching ambitions" are: 1) "to create the most competitive tax system in the G20"; 2) "to make the UK one of the best places in Europe to start, finance and grow a business" (p.5); 3) to stimulate investment and exports; 4) to "create a more educated workforce that is the most flexible in Europe". Human capital accumulation is notably last on this list and even then, the fourth point conflates two workforce objectives: skill accumulation and labour market flexibility. This last is to be achieved by ensuring the UK has the "Lowest burdens from employment regulation in the EU", while the business environment is to be improved by achieving "A lower domestic regulatory burden," amongst other policies (p.6).

<sup>2</sup>The OECD characterises regulation as a barrier to entrepreneurship. See e.g. OECD (2015), Figure 25, a graph entitled "There is scope to reduce barriers to entrepreneurship" plotting UK Product Market Regulation (PMR) scores against the average 'best' five OECD countries in terms of freedom from PMR.

percentage point reduction in tax and regulatory policy leads in simulation to an average higher growth rate of 0.09 percentage points per annum over 70 quarters.

The paper is structured as follows. A brief discussion of related work is provided in Section 2; the structural model is described in Section 3; Section 4 presents the empirical work, including discussion of data, methods and robustness checks; a policy reform experiment is given in Sections 5 and 6 concludes.

## 2 Related Work

Numerous models exist of how innovation raises productivity, and how policy can enter that process. In New Endogenous Growth theory, spillovers drive a wedge between private and social returns to innovation (Aghion and Howitt 1992; Romer 1990); such models recommend subsidies to research, while lowering barriers to entry (such as regulation and tax) has an ambiguous effect on innovation (Aghion and Howitt 2006; Acemoglu 2008). Related empirical work generally uses formal R&D expenditure and patent counts to proxy innovation (e.g. Jaumotte and Pain 2005) but since formal R&D is dominated by large established firms, this overlooks innovation by small and/or new businesses. Acs et al. (2009) refocus the growth driver on entrepreneurs:<sup>3</sup> entrepreneurship is decreasing in regulatory and administrative burdens and government “barriers to entrepreneurship” including labour market rigidities, taxes and bureaucratic constraints. In Braunerhjelm et al. (2010), the distribution of resources between R&D and entrepreneurship is as important to growth as purposeful R&D investments (cf. Michelacci 2003). The implication is that “Policy makers would be seriously misguided in focusing exclusively on knowledge creation” (Acs and Sanders 2013, p. 787) while ignoring the effective commercialisation of knowledge by entrepreneurs. This is a key factor in our modelling choices (on which we say more below); we allow for tax and regulatory policies to affect incentives to profit-motivated innovative activities that may include formal R&D but are not limited to it.

Empirical work on structural policy-growth relationships falls roughly into three categories: aggregate growth regressions (e.g. Erken et al. 2008; Acs et al. 2012; Djankov et al. 2006; Djankov et al. 2010), simulated reform exercises using calibrated DSGE models, and microeconomic studies on policy’s role in firm- or industry-level panels (see e.g. Scarpetta et al. 2002 and Myles 2009). Studies in the first category have serious difficulty establishing causality while the third category, though often more successful at addressing identification issues than macro-regressions, cannot reveal the macroeconomic impacts of policy. This motivates our DSGE-based approach, and we discuss the second category here.

Blanchard and Giavazzi (2003) derive a New Keynesian DSGE model in which product and labour market regulation affect the number of firms, employment and the real wage. Everaert and Schule (2008) and Gomes et al. (2011) use similar cal-

---

<sup>3</sup>In their model, investment in R&D by incumbent firms yields intratemporal spillovers which generate entrepreneurial opportunities

ibrated models to analyse the macroeconomic impact of structural reforms in EU countries. Regulatory reforms are treated as reductions in price and wage mark-ups in labour and product markets which lower product and labour market slack, stimulating employment and investment. Cacciatore and Fiori (2016) add search and matching frictions, allowing hiring and firing costs to be modelled in a less reduced-form fashion.

Coenen et al. (2008) use a calibrated two-country DSGE model (a version of the New Area-Wide Model) to investigate the macroeconomic effects of reforms to labour-market distorting tax rates, following the reasoning of Prescott (2004) that higher tax wedges in the euro area relative to the US explain differences in output, hours worked and labour productivity. They use the model to simulate the effect of reducing the tax wedge from European to US levels and find an increase in output and hours worked above 10%. Similarly, Poschke (2010), in a DSGE model with heterogeneous firms, finds that raising administrative entry costs from US to German levels (c. 30% of GDP per capita) reduces the difference between US and German TFP by about one third – a large impact. The reform reduces substitutability among differentiated goods (i.e. competition is reduced) and so markups rise and the market share of high productivity firms falls in general equilibrium. The calibrated model's performance is judged on whether it generates certain data features – a standard matching approach that has been called 'calibrationist' (Canova 1994, Chapter 3). Our empirical approach aligns us more closely with a growing macroeconomic literature concerned with estimating and formally evaluating DSGE models; see e.g. Schorfheide (2011) and Ruge-Murcia (2014). In using indirect inference methods and adopting the 'directed' Wald test (i.e. focusing the test on particular features of most interest, rather than testing the model in every dimension), our approach follows Le et al. (2011) – similar approaches are Dridi et al. (2007), Guerron-Quintana et al. (2017), and Hall et al. (2012).

### 3 Structural Model

As the backdrop for our investigation into the role of supply side policy in the growth process, we use an open economy<sup>4</sup> real business cycle model adapted from Meenagh et al. (2010). It is a two-country model, with one country modeled after the UK economy and the other representing the rest of the world; foreign prices and consumption demand are treated as exogenous, and international markets are cleared by the real exchange rate. The model omits many of the nominal and real frictions we are used to seeing in the standard New Keynesian framework, while still capturing UK real exchange rate movements (Meenagh et al. 2010). We are not alone in observing that “modern DSGE models need not embed large batteries of frictions and shocks to account for the salient features of postwar business cycles” (Ambler et al. 2012). Moreover, for an empirical analysis of the UK there is a clear advantage to

<sup>4</sup>The UK economy is highly open and an empirical study such as this must acknowledge that, though our principal focus is the behaviour of output and TFP.

abstracting from monetary policy which underwent numerous regime changes during this sample period. To emphasise, this simple DSGE model is intended as a vehicle within which to test empirically the central hypothesis about supply-side policy and economic growth using Indirect Inference methods.

Productivity is non-stationary (Eq. 27) and depends on time spent in innovative activity  $z_t$ , the consumer’s choice (cf. Lucas 1990). This activity is subject to a proportional cost due to government policy,  $\tau'_t$ ; this policy variable is subject to temporary but persistent shocks that generate long-lasting episodes of growth in TFP and output around balanced growth behaviour, via its incentive effects on  $z_t$ . In this paper,  $z_t$  is conceived of as entrepreneurship. A sizeable literature looks for a precise and workable definition of this ‘activity.’ Here we follow the synthesis definition of Wenekers and Thurik (1999), that entrepreneurship is the “ability and willingness [...] to perceive and create new economic opportunities [...] and to introduce their ideas in the market, in the face of uncertainty and other obstacles [...] it implies participation in the competitive process” (p. 46-47).<sup>5</sup> We discuss the growth process in more detail below.

### 3.1 Consumer Problem

The consumer chooses consumption ( $C_t$ ) and leisure ( $x_t$ ) to maximise lifetime utility,  $U$ :

$$U = \max E_0 \left[ \sum_{t=0}^{\infty} \beta^t u(C_t, x_t) \right] \tag{1}$$

$u(\cdot)$  takes the form:

$$u(C_t, x_t) = \theta_0 \frac{1}{(1 - \rho_1)} \gamma_t C_t^{(1-\rho_1)} + (1 - \theta_0) \frac{1}{(1 - \rho_2)} \xi_t x_t^{(1-\rho_2)} \tag{2}$$

$\rho_1, \rho_2 > 0$  are coefficients of relative risk aversion;  $\gamma_t$  and  $\xi_t$  are preference shocks;  $0 < \theta_0 < 1$  is consumption preference. The agent divides time among three activities: leisure, labour  $N_t$  supplied to the firm for real wage  $w_t$ , and activity  $z_t$  that is unpaid at  $t$  but known to have important future returns. The time endowment is:

$$N_t + x_t + z_t = 1 \tag{3}$$

Here the consumer chooses leisure, consumption, domestic and foreign bonds ( $b, b^f$ ) and bonds issued by the firm to finance its capital investment ( $\tilde{b}$ ), and new shares ( $S^p$ ) purchased at price  $q$ , subject to the real terms budget constraint.<sup>6</sup>

$$C_t + b_{t+1} + Q_t b_{t+1}^f + q_t S_t^p + \tilde{b}_{t+1} = w_t N_t - T_t + b_t(1 + r_{t-1}) + Q_t b_t^f (1 + r_{t-1}^f) + (q_t + d_t) S_{t-1}^p + (1 + \hat{r}_{t-1}) \tilde{b}_t \tag{4}$$

Taxbill  $T_t$  is defined further below. The only taxed choice variable in the model is  $z_t$ ; all other taxes are treated as lump sum to rule out wealth effects. Since the  $z_t$  choice is left aside until Section 3.4 on endogenous growth, the taxbill is not yet relevant.  $Q_t =$

<sup>5</sup>Otherwise, much of this description follows L. Minford and Meenagh (2019).

<sup>6</sup>Price  $P_t$  of consumption bundle is numeraire

$\frac{P_t^f}{P_t} \cdot \hat{E}_t$  gives relative consumer prices. The nominal exchange rate  $\hat{E}_t$  is assumed fixed, so  $Q_t$  is the relative import price.<sup>7</sup> Higher  $Q_t$  implies a real depreciation of domestic goods on world markets and hence an increase in competitiveness; this can be thought of as a real exchange rate depreciation.

The consumer’s first order conditions yield the Euler Eq. (5), the intratemporal condition (6),<sup>8</sup> real uncovered interest parity (7), and the share price formula (8). First order conditions on  $\tilde{b}_{t+1}$  and  $b_{t+1}$  combine for  $\hat{r}_t = r_t$ . Indeed, returns on all assets ( $S_t^p, b_{t+1}, \tilde{b}_{t+1}$  and  $b_{t+1}^f$ ) are equated.

$$\frac{1}{(1+r_t)} \gamma_t C_t^{-\rho_1} = \beta E_t[\gamma_{t+1} C_{t+1}^{-\rho_1}] \tag{5}$$

$$\frac{U_x}{U_c} |_{U=0} = \frac{(1-\theta_0)\xi_t x_t^{-\rho_2}}{\theta_0 \gamma_t C_t^{-\rho_1}} = w_t \tag{6}$$

$$(1+r_t) = E_t \frac{Q_{t+1}}{Q_t} (1+r_t^f) \tag{7}$$

$$q_t = \frac{q_{t+1} + d_{t+1}}{(1+r_t)} = \sum_{i=1}^{\infty} \frac{d_{t+i}}{\prod_{j=0}^{i-1} (1+r_{t+j})} \tag{8}$$

Equation 8 rests on the further assumption that  $q_t$  does not grow faster than the interest rate,  $\lim_{i \rightarrow \infty} \frac{q_{t+i}}{\prod_{j=0}^{i-1} (1+r_{t+j})} = 0$ .

The domestic country has a perfectly competitive final goods sector, producing a version of the final good differentiated from the product of the (symmetric) foreign industry. The model features a multi-level utility structure (cf. Feenstra et al. 2014). The level of  $C_t$  chosen above must satisfy the expenditure constraint,

$$C_t = p_t^d C_t^d + Q_t C_t^f \tag{9}$$

$p_t^d \equiv \frac{P_t^d}{P_t} \cdot C_t^d$  and  $C_t^f$  are chosen to maximise  $\tilde{C}_t$  via the following utility function (Eq. 10), subject to the constraint that  $\tilde{C}_t \leq C_t$ .

$$\tilde{C}_t = [\omega (C_t^d)^{-\rho} + (1-\omega) \zeta_t (C_t^f)^{-\rho}]^{-\frac{1}{\rho}} \tag{10}$$

At a maximum the constraint binds;  $0 < \omega < 1$  denotes domestic preference bias. Import demand is subject to a shock,  $\zeta_t$ . The elasticity of substitution between domestic and foreign varieties is constant at  $\sigma = \frac{1}{1+\rho}$ . First order conditions imply the relative demands for the imported and domestic goods:

$$\frac{C_t^f}{C_t} = \left( \frac{(1-\omega)\zeta_t}{Q_t} \right)^\sigma \tag{11}$$

<sup>7</sup> $b_{t+1}^f$  is a real bond - it costs what a unit of the foreign consumption basket ( $C_t^*$ ) would cost, i.e.  $P_t^*$  (the foreign CPI). In domestic currency, this is  $P_t^* \hat{E}_t$ . Assuming  $P_t^* \simeq P_t^f$  (i.e. exported goods from the home country have little impact on the larger foreign country) the unit cost of  $b_{t+1}^f$  is  $Q_t$ .

<sup>8</sup>Later we show that the return on labour time,  $w_t$ , is equal at the margin to the return on  $\zeta_t$ .

$$\frac{C_t^d}{C_t} = \left( \frac{\omega}{p_t^d} \right)^\sigma \tag{12}$$

Given Eq. 11 above, the symmetric equation for foreign demand for domestic goods (exports) relative to general foreign consumption is

$$(C_t^d)^* = C_t^* \left( (1 - \omega^F) \zeta_t^* \right)^{\sigma^F} (Q_t^*)^{-\sigma^F} \tag{13}$$

\* signifies a foreign variable;  $\omega^F$  and  $\sigma^F$  are foreign equivalents to  $\omega$  and  $\sigma$ .  $Q_t^*$  is the foreign equivalent of  $Q_t$ , import prices relative to the CPI, and  $\ln Q_t^* \simeq \ln p_t^d - \ln Q_t$ .<sup>9</sup> An expression for  $p_t^d$  as a function of  $Q_t$  follows from the maximised Eq. 10:

$$1 = \omega^\sigma (p_t^d)^{\rho\sigma} + [(1 - \omega)\zeta_t]^\sigma Q_t^{\rho\sigma} \tag{14}$$

A first order Taylor expansion around  $p^d \simeq Q \simeq \zeta \simeq 1$ , with  $\sigma = 1$ , yields a loglinear approximation for this:

$$\ln p_t^d = \hat{k} - \frac{1 - \omega}{\omega} \frac{1}{\rho} \ln \zeta_t - \frac{1 - \omega}{\omega} \ln Q_t \tag{15}$$

The export demand equation is then

$$\ln(C_t^d)^* = \check{c} + \ln C_t^* + \sigma^F \frac{1}{\omega} \ln Q_t + \varepsilon_{ex,t} \tag{16}$$

where  $\check{c}$  collects constants and  $\varepsilon_{ex,t} = \sigma^F [\ln \zeta_t^* + \frac{1-\omega}{\omega} \frac{1}{\rho} \ln \zeta_t]$ . Assuming no capital controls, the real balance of payments constraint is satisfied.

$$\Delta b_{t+1}^f = r_t^f b_t^f + \frac{p_t^d E X_t}{Q_t} - I M_t \tag{17}$$

### 3.2 Firm Problem

The representative firm produces the final good via a Cobb Douglas function with constant returns to scale and diminishing marginal returns to labour and capital, where  $A_t$  is total factor productivity:

$$Y_t = A_t K_t^{1-\alpha} N_t^\alpha \tag{18}$$

The firm undertakes investment, purchasing new capital via debt issue ( $\tilde{b}_{t+1}$ ) at  $t$ ; the cost  $\hat{r}_t$  is payable at  $t + 1$ . Bonds are issued one for one with capital units demanded:  $\tilde{b}_{t+1} = K_t$ . There are convex adjustment costs to capital. The cost of capital covers the return demanded by debt-holders, capital depreciation  $\delta$  and adjustment costs,  $\tilde{a}_t$ .<sup>10</sup> The profit function is:

$$\pi_t = Y_t - \tilde{b}_{t+1}(\hat{r}_t + \delta + \kappa_t + \tilde{a}_t) - (\tilde{w}_t + \chi_t)N_t$$

<sup>9</sup>  $Q_t^* = \frac{p_t^d}{P_t^*}$  - since  $Q_t = \frac{P_t^f}{P_t}$  and  $P_t$  is numeraire,  $Q_t = P_t^f$ . If domestic export prices hardly influence the foreign CPI then  $P_t^* \simeq P_t^f$ .

<sup>10</sup>The adjustment cost attached to  $\tilde{b}_{t+1}$  is:  $\tilde{b}_{t+1}\tilde{a}_t = \tilde{b}_{t+1} \cdot \frac{1}{2} \zeta \left( \tilde{b}_{t+1} + \frac{\tilde{b}_t^2}{\tilde{b}_{t+1}} - 2\tilde{b}_t \right) = \frac{1}{2} \zeta (\Delta \tilde{b}_{t+1})^2$

$\tilde{w}_t$  is the real unit cost of labour;  $\kappa_t$  and  $\chi_t$  are cost shocks capturing random movements in marginal tax rates. From the consumer first order conditions,  $\hat{r}_t = r_t$ . Substituting for this and for  $\tilde{b}_{t+1} = K_t$ , profits are:

$$\pi_t = Y_t - K_t(r_t + \delta + \kappa_t) - \frac{1}{2}\zeta(\Delta K_t)^2 - (\tilde{w}_t + \chi_t)N_t \tag{19}$$

Here adjustment costs are explicit, having substituted  $\tilde{b}_{t+1}\tilde{a}_t = K_t\tilde{a}_t = \frac{1}{2}\zeta(\Delta K_t)^2$ . Parameter  $\zeta$  is constant.

The firm chooses  $K_t$  and  $N_t$  to maximise expected profits, taking  $r_t$  and  $\tilde{w}_t$  as given. Assume free entry and a large number of firms operating under perfect competition. The optimality condition for  $K_t$  equates the marginal product of capital (net of adjustment costs and depreciation) to its price, plus cost shock  $-d$  is the firm's discount factor. Rearranged, this gives a non-linear difference equation in capital.

$$K_t = \frac{1}{1+d}K_{t-1} + \frac{d}{1+d}E_tK_{t+1} + \frac{(1-\alpha)Y_t}{\zeta(1+d)K_t} - \frac{1}{\zeta(1+d)}(r_t + \delta) - \frac{1}{\zeta(1+d)}\kappa_t \tag{20}$$

Given capital demand, the firm's investment,  $I_t$ , follows via the capital accumulation identity.

$$K_t = I_t + (1 - \delta)K_{t-1} \tag{21}$$

The optimal labour choice gives the firm's labour demand condition:

$$N_t = \alpha \cdot \frac{Y_t}{\tilde{w}_t + \chi_t} \tag{22}$$

Internationally differentiated goods introduce a wedge between the consumer real wage,  $w_t$ , and the real labour cost for the firm,  $\tilde{w}_t$ .<sup>11</sup> The wedge is  $p_t^d = \frac{w_t}{\tilde{w}_t}$ , implying, via 15, the following:

$$\ln w_t = \hat{k} + \ln \tilde{w}_t - \frac{1-\omega}{\omega} \ln Q_t - \frac{1-\omega}{\omega} \frac{1}{\rho} \ln \varsigma_t \tag{23}$$

### 3.3 Government

The government spends on the consumption good ( $G_t$ ) subject to its budget constraint.

$$G_t + b_t(1 + r_{t-1}) = T_t + b_{t+1} \tag{24}$$

Spending is assumed to be non-productive (transfers). As well as raising tax revenues  $T_t$  the government issues one-period bonds. Each period, revenues cover spending and the current interest bill:  $T_t = G_t + r_{t-1}b_t$  so  $b_t = b_{t+1}$ . Revenue  $T_t$  is as follows.

$$T_t = \tau_t z_t + \Phi_t \tag{25}$$

$\tau_t$  is a proportional rate on time spent in innovative activity  $z_t$ . Assuming that all policy costs on  $z_t$  are genuine external social costs redistributed to the consumer via a reduction in the lumpsum levy  $\Phi_t$ , tax revenue collected by government is equal

<sup>11</sup>The firm's real cost of labour is the nominal wage  $W_t$  relative to domestic good price,  $P_t^d$ , while the real consumer wage is  $W_t$  relative to the general price  $P_t$ .

to that taxbill paid by consumers.<sup>12</sup> Lumpsum tax  $\Phi_t$  captures revenue effects of all other tax instruments, responding to changes in  $\tau_t z_t$  for revenue neutrality in the government budget constraint. Government spending is modeled as an exogenous trend stationary AR(1) process, where  $|\rho_g| < 1$  and  $\eta_{g,t}$  is a white noise innovation.

$$\ln G_t = g_o + g_1 t + \rho_g \ln G_{t-1} + \eta_{g,t} \tag{26}$$

### 3.4 Productivity Growth

Productivity growth is a linear function of time spent in an activity  $z_t$ , where  $a_1 > 0$ :

$$\frac{A_{t+1}}{A_t} = a_0 + a_1 z_t + u_t \tag{27}$$

Policy,  $\tau'_t$ , drives growth systematically through  $z_t$ .<sup>13</sup> This section derives the linear relationship between productivity growth and  $\tau'_t$  driving the model's dynamic behaviour in simulations. We adapt the endogenous growth process from Meenagh et al. (2007) to a decentralised framework. It resembles Lucas (1990) in that the agent can invest time in a growth-driving activity.<sup>14</sup>

The consumer chooses  $z_t$  to maximise utility (Eqs. 1 and 2), subject to Eqs. 3, 4 and 25. Assume for the consumer's shareholdings that  $S_t^p = \bar{S} = 1$ .<sup>15</sup> The rational agent expects  $z_t$  to raise her consumption possibilities through her role as the firm's sole shareholder, knowing that, given Eq. 27, a marginal change in  $z_t$  permanently raises productivity from  $t + 1$ . This higher productivity is fully excludable and donated to the atomistic firm she owns; higher productivity is anticipated to raise household income via firm profits paid out as dividends,  $d_t$  (everything leftover from revenue after labour and capital costs are paid). The choice is thought not to affect economy-wide aggregates; all prices are taken as parametric (note that the productivity increase is not expected to increase the consumer real wage here, though it does so in general equilibrium - cf. Boldrin and Levine (2002, 2008)).<sup>16</sup>

Rearranging the first order condition with respect to  $z_t$  (see Appendix A for full derivation), the expression can be approximated as

$$\frac{A_{t+1}}{A_t} = a_1 \cdot \frac{\frac{\beta \rho_Y}{1 - \beta \rho_Y} \cdot \frac{Y_t}{C_t}}{\frac{w_t}{C_t} (1 + \tau'_t)} \tag{28}$$

<sup>12</sup>It is possible that only a proportion  $0 < \psi < 1$  of the penalty paid on  $z_t$  enters the government budget as revenue, the rest being deadweight loss that reduces the payoff to innovation without benefiting the consumer in other ways. In that case revenue is  $\bar{T}_t = \psi \tau_t z_t + \Phi_t$  while the consumer tax bill is  $T_t = \tau_t z_t + \Phi_t$ . Here  $\psi$  is assumed to be 1, though notionally it could vary stochastically.

<sup>13</sup>All other factors - e.g. human capital or firm specific R&D investment - are in the error term.

<sup>14</sup>In Lucas' model, human capital accumulation increases labour efficiency and future earnings. The trade-off is between time spent in this productivity-enhancing activity and ordinary labour, which yields the current wage immediately.

<sup>15</sup>This allows the substitution in the budget constraint that  $q_t S_t^p - (q_t + d_t) S_{t-1}^p = -d_t$ .

<sup>16</sup>Given the time endowment  $1 = N_t + x_t + z_t$ , the agent has indifference relations between  $z_t$  and  $x_t$ , between  $x_t$  and  $N_t$ , and  $z_t$  and  $N_t$ . The intratemporal condition in 6 gives the margin between  $x_t$  and  $N_t$ ; here we focus on the decision margin between  $z_t$  and  $N_t$ , so the margin between  $z_t$  and  $x_t$  is implied. Therefore the substitution  $N_t = 1 - x_t - z_t$  can be made in the budget constraint.

This is in terms of  $\frac{\tau_t}{w_t} \equiv \tau'_t$ , the ratio of  $\tau_t$  to the wage (the opportunity cost of  $z_t$ ).  $\tau'_t$  is a unit free rate unlike  $\tau_t$  which, like the wage, is a rate per unit of time. A first order Taylor expansion around  $\tau'_t = \tau'$  of Eq. 28 gives the following linear relationship:

$$d \ln A_{t+1} = b_0 + b_1 \tau'_t + \varepsilon_{A,t} \quad (29)$$

$b_1 = -a_1 \cdot \frac{\beta \rho \gamma}{C} \frac{Y}{w_t (1 + \tau')^2} < 0$  for a policy raising the costs of innovation.<sup>17</sup> At this point, we revisit our conception of entrepreneurship which is admittedly broad. Our entrepreneurship growth channel encompasses business activities which push forward the production possibility frontier (the creative responder/destructor identified by Schumpeter (1947, 1942)) or raise the average productivity level in the economy (the arbitrageur emphasized by Kirzner (1973)), perhaps by implementing foreign technologies at home. There is no explicit entry or exit in this model, and no international spillover. To reiterate, the share-holder entrepreneur donates ideas resulting from  $z_t$  to her firm, capturing the full return to  $z_t$ , except for taxes and regulatory costs. Non-rival technology – leading to costless spillovers – and fixed innovating costs lead many to discard perfect competition as a viable framework for examining innovation. However, Boldrin and Levine (2008, 2002) argue against costless spillovers. Returns to technological progress generated by the entrepreneur may accrue formally to fixed factors of production, rather than appearing as supernormal profits; this is what happens in our model, while also the individual entrepreneur/owner acts taking prices and costs as parametric. This model provides a framework in which to test the hypothesis of interest: whether a causal relationship from supply-side policy ‘barriers’ to economic growth exists in the UK macroeconomic data. If a relationship from policy to growth is found, it is left to future work to examine which process drives it by defining the microstructure more minutely.

To close this section, we outline the implications of policy incentives for labour in the model. Equations 28 and 27 relate  $z_t$  to  $\tau'_t$ . Define  $\frac{\partial z_t}{\partial \tau'_t} \equiv c_1$ , a constant parameter featuring in the producer labour cost equation:

$$\ln \tilde{w}_t = const_4 + \rho_2 \ln N_t + \rho_1 \ln C_t + \left[ \frac{1 - \omega}{\omega} \right]^\sigma \ln Q_t + \rho_2 2c_1 \tau'_t + e_{w,t} \quad (30)$$

where  $e_{w,t} = -\ln \gamma_t + \ln \xi_t + \frac{1}{\rho} \left[ \frac{1 - \omega}{\omega} \right]^\sigma \ln \zeta_t$ . This equation is derived from the intratemporal condition (Eq. 6 - see Appendix A for full derivation).  $\tau'_t$  penalises  $z_t$ , so  $c_1 < 0$ , hence  $\frac{d \ln \tilde{w}_t}{d \tau'_t} < 0$  or  $\frac{d \ln N_t}{d \tau'_t} > 0$ . Equation 30 is the rearranged labour supply condition; the worker responds to a higher penalty on  $z_t$  by raising labour time.<sup>18</sup>

<sup>17</sup>Other terms in the expansion are treated as part of the error term.

<sup>18</sup>Substituting into Eq. (28) from (27), rearranging for  $z_t$ , then taking the derivative with respect to  $\tau'_t$ , we find  $c_1 = -\frac{\beta \rho \gamma}{C} \frac{Y}{w_t (1 + \tau')^2}$ ; we could potentially calibrate  $c_1$  from this, taking appropriate values for righthand side variables. However there is flexibility around what values are ‘appropriate’. The same is true for  $b_1$ .

### 3.5 Closing the Model

Goods market clearing in volume terms is:

$$Y_t = C_t + I_t + G_t + EX_t - IM_t \tag{31}$$

All asset markets also clear.

A transversality condition rules out balanced growth financed by insolvent borrowing rather than growing fundamentals. The balance of payments is restricted so that the long run change in net foreign assets (the capital account) is zero. At a notional date  $T$  when the real exchange rate is constant, the cost of servicing the current debt is met by an equivalent trade surplus.

$$r_T^f b_T^f = - \left( \frac{p_T^d \cdot EX_T}{Q_T} - IM_T \right) \tag{32}$$

The numerical solution path is forced to be consistent with the constraints this condition places on the rational expectations. In practice it constrains household borrowing since government solvency is ensured already, and firms do not borrow from abroad. When solving the model, the balance of payments constraint is scaled by output so that the terminal condition imposes that the ratio of debt to gdp must be constant in the long run,  $\Delta \hat{b}_{t+1}^f = 0$  as  $t \rightarrow \infty$ , where  $\hat{b}_{t+1}^f = \frac{b_{t+1}^f}{Y_{t+1}}$ . The model is loglinearised before solution and simulation; the full model listing is in Appendix B.

### 3.6 Exogenous Variables

Stationary exogenous variables consist of shocks to real interest rates (Euler equation), labour demand, real wages, capital demand, export demand and import demand. These are not directly observed but are implied as the difference between the data and the model predictions (cf. the ‘wedges’ of Chari et al. (2007)). Those differences  $e_{i,t}$ , which we call structural residuals or shocks, are treated as trend stationary AR(1) processes:

$$e_{i,t} = a_i + b_i t + \rho_i e_{i,t-1} + \eta_{i,t} \tag{33}$$

$\eta_{i,t}$  is an i.i.d mean zero innovation term;  $i$  identifies the shock. We model foreign consumption demand, government consumption, foreign interest rates and policy variable  $\tau_t'$  similarly. AR(1) coefficients  $\rho_i$  are estimated. Where expectations enter, they are estimated using a robust instrumental variable technique (Wickens 1982; McCallum 1976); they are the one step ahead predictions from an estimated VECM. We do not stationarise any of the endogenous variables and so the exogenous shocks (wedges) extracted from each structural equation are either stationary, trend-stationary, or non-stationary in the case of TFP. Where  $a_i \neq 0$  and  $b_i \neq 0$ , the detrended residual  $\hat{e}_i$  is used:

$$\hat{e}_{i,t} = \rho_i \hat{e}_{i,t-1} + \eta_{i,t} \tag{34}$$

$$\hat{e}_{i,t} = e_{i,t} - \hat{a}_i - \hat{b}_i t \tag{35}$$

The innovations  $\eta_{i,t}$  are approximated by the fitted residuals from estimation of Eq. 34,  $\hat{\eta}_{i,t}$ . The Solow residual  $\ln A_t$  is modelled as a unit root process with drift

driven by a stationary AR(1) shock and by the detrended exogenous variable  $\tau'_t$ , following Eq. 29.

$$\ln A_t = d + \ln A_{t-1} + b_1 \tau'_{t-1} + e_{A,t} \quad (36)$$

$$e_{A,t} = \rho_A e_{A,t-1} + \eta_{A,t} \quad (37)$$

Deterministic trends are removed from exogenous variables since they enter the model's balanced growth path. We focus here on how the economy deviates from steady state in response to shocks - in particular, stationary innovations to the policy variable,  $\tau'_t$ . Such innovations will have a permanent shift effect on the path of TFP via its unit root. Due to their persistence they also generate transitional TFP growth episodes above long-run trend. Note that, were  $\tau'_t$  to be non-stationary, it would cause simulated output to be I(2) which is not empirically defensible. We discuss this treatment of  $\tau'$  further in Sections 4.1.2 and 4.2.2 below.

## 4 Empirical Work

This empirical work is an application of the Indirect Inference testing method given in Le et al. (2011). The method involves simulating the DSGE model by repeated resampling of the shocks implied by the data, and then comparing the properties of these model-generated simulations with the actual data. For that comparison we use a theory-neutral descriptive model, the 'auxiliary model,' from which a formal test statistic is derived. Our choice of auxiliary model and the method we apply, along

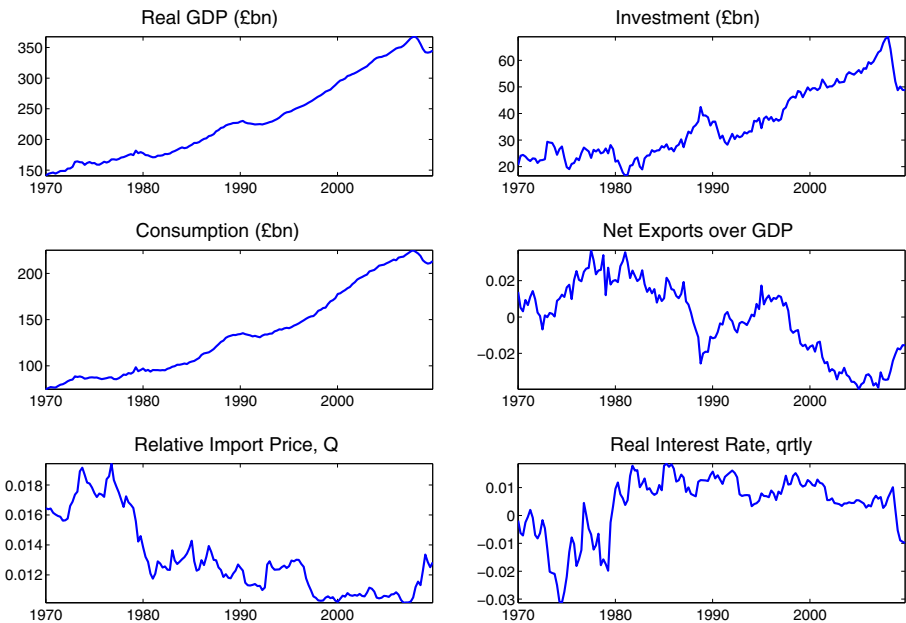

Fig. 1 Key quarterly UK data (real)

with an exploration of its small sample properties, are discussed further below, though we refer readers to the recent surveys in this journal for a more in-depth treatment (Le et al. 2016; Meenagh et al. 2019).

## 4.1 Data

### 4.1.1 Macroeconomic Data for the UK

The sample is unfiltered UK macroeconomic data for 1970 to 2009; key series are plotted in Fig. 1 (sources in Appendix). In this model, shocks to policy can have long-lasting transitional effects on endogenous variables, and such shocks are occasionally large. In both cases the HP filter distorts the estimates of underlying trends (Hodrick and Prescott 1997); where we would want to analyse the model's adjustment to the policy shock, the HP filter may interpret it as a change in underlying potential and remove it. For further discussion of the problems induced by filtering, see e.g. Hamilton (2018). Given our non-stationary data, we choose a Vector Error Correction Model as the auxiliary model - this is discussed further in Section 4.2.1 below.<sup>19</sup>

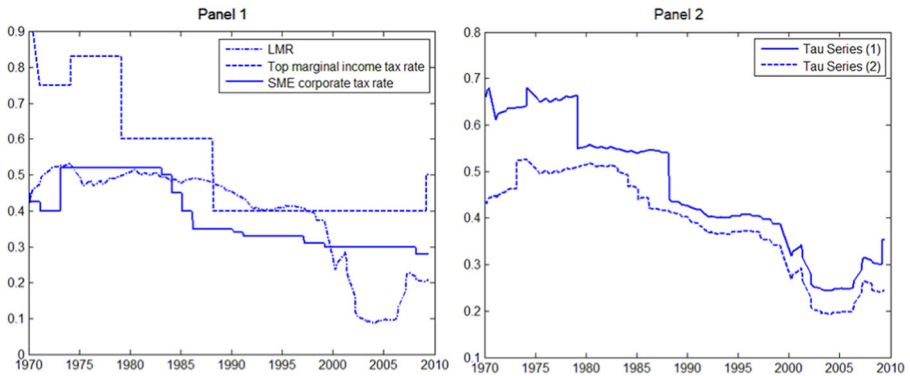

### 4.1.2 Data for Policy Variable

For policy indicator  $\tau_t'$  we collect UK data on regulation and tax, two key components of the business environment. On regulation, the focus is on the labour market; we use an index of centralized collective bargaining (CCB) produced by the World Economic Forum and a mandated cost of hiring index (MCH) from the World Bank Doing Business project; the latter reflects the costs of social security and other benefits such as holiday pay. More detail is given in Appendix C.1. Taking the trade union membership rate we interpolate the lower frequency indices using the Denton proportionate variant adjustment method (Denton 1971). An equally weighted arithmetic average of the resulting quarterly series for collective bargaining and mandated hiring costs gives the labour market regulation (LMR) indicator used here to reflect labour market inefficiency; see Fig. 2, Panel 1.<sup>20</sup>

In the absence of a good 'effective' entrepreneur tax rate for 1970-2009, which is prohibitively complex to calculate, we use the top marginal income tax rate. This is not to say that every entrepreneur gets into the top income tax bracket; the expected return to entrepreneurship is generally small. This top marginal tax rate is a proxy for

<sup>19</sup>The model is solved using the Extended Path Algorithm similar to Fair and Taylor (1983), which ensures that the one period ahead expectations are consistent with the model's own predictions. Additionally, the expectations satisfy terminal conditions which ensure that simulated paths for endogenous variables converge to long run levels consistent with the model's own long run implications. These long run levels depend on the behaviour of the non-stationary driving variables (TFP and net foreign assets) as they evolve stochastically over the simulation period (deterministic trend behaviour is removed).

<sup>20</sup> $\tau_t'$  excludes other types of regulation as data going back to 1970 is unavailable. However, the indices we use are highly correlated with the OECD index of product market regulation - see Appendix for further discussion.

**Fig. 2** Proxy indicators for policy barriers to entrepreneurship (Panel 2) and their components (Panel 1)

the profit motive central to the notion of entrepreneurship as we have defined it; cf. Lee and Gordon (2005). See also e.g. Balamoune-Lutz and Garelo (2014) who find that a reduction in marginal tax rates at the top of the income distribution relative to the marginal tax rate at average earnings increases entrepreneurship.

The top marginal income tax rate is measured annually; the series is interpolated to a quarterly frequency by constant match. The series falls consistently until 2009 with the introduction of the 50p tax rate on income over \$150,000 (Fig. 2, Panel 1). The main policy indicator used in empirical work is an equally weighted average of top marginal income tax and labour market regulation (Tau Series (1), Fig. 2 Panel 2). The SME rate of corporation tax may well belong in  $\tau'_t$ ; reductions in this rate lower the costs of running a new business. However, reducing corporation tax relative to other forms of taxation (employee or self-employed labour income) could distort incentives to incorporate at the small end of the firm size distribution for reasons unrelated to productivity growth. For instance, incorporation soared in the UK after the 2002 Budget when the starting rate on corporate profits up to \$10,000 was reduced to zero (Crawford and Freedman 2010). Corporation tax is therefore excluded from the main  $\tau'_t$  index. However, an alternative policy variable constructed from the labour market indicator and corporation tax rates (in place of top marginal income tax) is investigated in Section 4.4.1 (Tau Series (2), Fig. 2, Panel 2).

The index falls over the sample, irregularly due to steps in marginal income tax.<sup>21</sup> In our model of productivity growth  $\tau'$  is modelled exogenously as a stationary stochastic series with high persistence, i.e. before solving the model a linear trend term is estimated and removed, leaving the detrended  $\tau'_t$  rate (see Section 3.6). We can justify this in two ways. Either the trend in  $\tau'$  is fully offset by other deterministic factors affecting TFP in the long run, or (our preferred assumption) the trend that we estimate in our sample is not a true long run trend.  $\tau'$  could not continue indefinitely along its sample trend, since this would imply tax/regulative levels going to minus infinity. The policy variable is by definition bounded between 0 and 1, and theoretically it should be stationary in the very long run. There are sound political

<sup>21</sup>KPSS and ADF test results support the decision to treat the series as trend stationary.

**Fig. 3** Detrended policy variable; log change in TFP

economy arguments to say that such policies should be modelled as persistent AR(1) series which stabilise around a long-run positive mean (hitting the zero lower bound and staying there is politically infeasible for this variable).

An implication of this treatment is that the economy has a constant balanced growth path along the lines of a standard neoclassical growth model, since the growth of productivity is constant apart from the stationary shocks to  $\tau'$  and the residual error. The detrended series is plotted against the changes in the Solow residual (in logs) in Fig. 3. This shows some significant movements around trend in the policy variable and the interest is in whether such movements cause the behaviour of productivity. Since our results may be sensitive to the choice of detrending procedure, we conduct robustness tests on this in Section 4.4.1.

## 4.2 Indirect Inference Methods

See Le et al. (2016) for a full explanation of the methodology. Here we give a brief overview.  $J$  bootstrap samples are generated from the DSGE model and some parameter set  $\theta$ . Each sample is estimated using an auxiliary model, yielding coefficient vectors  $a_j$  for  $j = 1, \dots, J$ . Using the variance-covariance matrix  $\Omega$  for the distribution of  $a_j$  implied by the structural model and  $\theta$ , we construct the small-sample distribution for the Wald statistic,  $WS(\theta) = (a_j - \overline{a_j(\theta)})' W(\theta) (a_j - \overline{a_j(\theta)})$ , where  $\overline{a_j(\theta)}$  is the mean of the  $J$  estimated vectors and  $W(\theta) = \hat{\Omega}(\theta)^{-1}$ . The same auxiliary model is estimated with the observed data, yielding vector  $\hat{\alpha}$ . The test statistic is then  $WS^*(\theta) = (\hat{\alpha} - \overline{a_j(\theta)})' W(\theta) (\hat{\alpha} - \overline{a_j(\theta)})$ . A  $WS^*(\theta)$  falling in the 95th percentile of the distribution or above implies a rejection of the structural model with  $\theta$  at 5% significance. The Wald percentile can be converted into an equivalent t-statistic<sup>22</sup> or p-value.

<sup>22</sup>Since the Wald is a chi-squared, the square root is asymptotically a normal variable.

This Wald test procedure is the basis for estimation. Within a bounded parameter space an algorithm searches for a parameter set,  $\theta$ , which minimises the Wald percentile for this structural model.

#### 4.2.1 Auxiliary Model

The DSGE model solution can be written as a cointegrated VECM – we rearrange and approximate this as a VARX(1); see Appendix. This approximation to the structural model's reduced form is the unrestricted auxiliary model used in the indirect inference Wald test (Eq. 38).

$$y_t = [I - K]y_{t-1} + K\Pi x_{t-1} + n + \phi t + q_t \quad (38)$$

$t$  captures the deterministic trend in  $\bar{x}_t$  (the balanced growth behaviour of the exogenous variables) affecting endogenous and exogenous variables (respectively  $y_t$  and  $x_t$ ). Lagged difference regressors are in the error  $q_t$ . Unit root variables,  $x_{t-1}$ , control for permanent effects of past shocks on  $x$  and  $y$ . Our research question is whether tax and regulation play a causal role in determining TFP and output growth, so these are initially the endogenous variables in the auxiliary VARX(1). This is therefore a 'directed' Wald test (Le et al. 2011). The policy variable  $\tau'_{t-1}$  and net foreign assets  $b_{t-1}^f$  are included as lagged exogenous variables; unit root variable  $b_{t-1}^f$  captures the model's stochastic trend.<sup>23</sup>

Vector  $\hat{\alpha}$  contains OLS estimates of the coefficients on observed data for these lagged endogenous and exogenous variables plus the auxiliary model error variances. The vector  $a_j$  is composed similarly and used to construct the Wald distribution. Auxiliary model errors are checked for stationarity. Though the trend term must be present to capture deterministic behaviour, we focus on the stochastic behaviour induced by the shocks and therefore exclude the deterministic trend from the test. We expand on this further below.

#### 4.2.2 Dealing with Balanced Growth Behaviour

The model's balanced growth path is its deterministic behaviour in the absence of stochastic shocks and with all long run conditions imposed. In the theoretical model, the deterministic behaviour of each endogenous variable along the BGP is a combination of the true deterministic trends in the exogenous variables, including (indeed principally) the exogenous trend in the I(1) TFP process. The deterministic trend behaviour implied by the model's long run solution can be calculated and added back

<sup>23</sup>Though this is a significant approximation to the full solution, it is still a demanding test of the model which must match the joint behaviour of output and TFP, conditional on the non-stationary predetermined variable  $b_{t-1}^f$  and on  $\tau'$ . Moreover, this level of approximation in the auxiliary model does not affect the power of the test (see Section 4.3; or the small sample properties of Indirect Inference in general, see Le et al. (2011) and Le et al. (2016)).

into the simulated data, using the sample estimates for the exogenous variable trends in place of the true trends.

In the actual data and also in our model-simulated samples with deterministic behaviour added back in, there are both deterministic and stochastic trend components in the endogenous variables. In the auxiliary VECM used as the descriptive basis for the test, the combination of deterministic trends in the exogenous variables would be captured by the deterministic trend term, while stochastic trends are captured by the non-stationary variables. As noted above, temporary shocks to  $\tau'$  have a permanent effect on I(1) productivity, which explains why  $\tau'$  has such a large effect on long run output (see Table 5).

However, though we allow for the deterministic trend in the VECM, in testing the model we ignore its coefficient. We rely for the test on the 'dynamic terms' in the VECM, relating output and productivity to each other. These provide high statistical power as our Monte Carlo experiments show (see Section 4.3 below). Adding in the trend terms from the model would diminish this power because there are many and when combined would have a very large standard error, making it too easy for the model to match the estimated output trend in the VECM.

Indeed, we would emphasise the well-understood point that these sample trends do not necessarily apply in the long run. For example  $\tau'$ , as discussed above in Section 4.1.2, cannot continue on a strong downward trend indefinitely without absurd implications. Hence, another of the long-run conditions imposed when we calculate the balanced growth path for the model is that these trends are not very long run (population) trends. Effectively this means that the balanced growth behaviour of our model is like any neoclassical exogenous growth model in that the deterministic trend in TFP is exogenous; though in theory it would be affected by a deterministic trend in  $\tau'$ , we assume that in the very long run the trend in  $\tau'$  is zero.

### 4.3 Test Power and Model Identification

#### 4.3.1 Power Exercise for the Indirect Inference Wald Test

Since the Wald test is the basis for the estimation process, the results below and the associated variance decomposition and simulated policy reform rely for their validity on its power to reject misspecified models. In other macro-modelling applications the test's power has been found to be considerable; see Le et al. (2016). Here we investigate the power of the test exactly as it has been applied here for this particular model via a Monte Carlo exercise. Table 1 reports the rejection rates when the DSGE model parameters are perturbed away from their true values (randomly up or down)

**Table 1** Rejection rates, all coefficients falsified together

Falseness, $\theta$ (%)	None	0.50	1.00	1.50	2.00	2.50	3.00	3.50
Rejection rate(%)	5	5.66	5.76	6.44	9.10	29.48	99.30	100.00

to an increasing extent.<sup>24</sup> We find that structural coefficients 3% away from true are rejected by the test 99.3% of the time, while 3.5% falseness leads to rejection 100% of the time.

We would also like to know how often the test will reject a model when just a few of the coefficients are misspecified. The coefficients of most interest here are  $b_1$  and  $c_1$ , since they determine the importance of the policy variable we have added into the model. The power exercise is therefore repeated when these two coefficients alone are falsified; we are particularly interested in picking up on falseness as the coefficient gets closer to zero, so that we can be sure that policy is significant in the model. When these two coefficients alone are 50% false (in the direction of zero), the model is rejected 99.08% of the time. This provides a ‘worst case’ bound for our estimates of these parameters; in practice it is unlikely that all other coefficients would have zero misspecification.

### 4.3.2 Model Identification

We also formally test the model’s identification using the numerical test developed by Le et al. (2017), again using Monte Carlo methods. A true model is used to create numerous large samples, and the identification test checks whether another parameter set can generate the same auxiliary model distribution as the true model, by comparing the Indirect Inference Wald test rejection rates for true versus alternative parameterisations. If some alternative model is rejected 5% of the time (i.e. at the same rate as the true model) the model cannot be identified, as this occurs only when the reduced form descriptions of true and alternative models are indistinguishable. For a full explanation of the procedure, see Le et al. (2017).<sup>25</sup>

We find that structural parameters are rejected 100% of the time when 1% away from true. When 0.7% away from the true set, alternative models are rejected 99.88% of the time. These results on identification and test power give an idea of the reliability of the method and of the estimation results which follow.

## 4.4 Estimation and Test Results

Table 2 presents structural coefficients that are held fixed throughout the analysis. Long run ratios  $\frac{M}{Y}$ ,  $\frac{X}{Y}$ ,  $\frac{Y}{C}$  and  $\frac{G}{C}$  are set to UK post-war averages; these then imply values for  $\frac{X}{C}$  and  $\frac{M}{C}$ . The rest are calibrated from Meenagh et al. (2010). Other parameters in the DSGE model are estimated via the Indirect Inference procedure. The estimates for this model, with  $\tau(1)$  as the policy variable driving productivity, are given in Table 3. The associated Wald percentile is 72, equivalent to a p-value

<sup>24</sup>For example, if coefficient  $\rho_2$  is 1.2 then inducing falseness by +3% means setting it at 1.236.

<sup>25</sup>The auxiliary model used for the test is a 5 variable VARX(4); the fuller auxiliary model is used in order to be a closer approximation of the DSGE model’s solution.

**Table 2** Structural model parameters fixed throughout study

Labour share, $\alpha$	0.7	$K/C$	0.196	$Y/K$	0.33
Discount factor, $\beta$	0.97	$Y/C$	1.732	$X/Y$	0.208
Depreciation rate, $\delta$	0.0125	$M/C, X/C, G/C$	0.37,0.36,0.44	$M/Y$	0.213

of 0.28, well within the non-rejection area of the bootstrap distribution. The implied AR(1) coefficients for the exogenous variables are reported in Table 4.<sup>26,27</sup>

A full set of impulse response functions was obtained for every shock in the model; the model generates standard RBC behaviour with this parameter set. The estimated import and export elasticities sum to 2.337, satisfying the Marshall-Lerner condition.<sup>28</sup> They are also consistent with US estimates obtained by Feenstra et al. (2014), and with UK estimates from Hooper et al. (2000). Given the long run constraint on the capital equation that  $\zeta_3 = 1 - \zeta_1 - \zeta_2$ , only  $\zeta_1$  and  $\zeta_2$  were estimated freely. The estimated capital equation coefficients imply a strong pull of past capital on the current value (0.636), indicating high adjustment costs, while the lower estimate of the coefficient on expected capital,  $\zeta_2$ , at 0.335 implies a discount rate for the firm far higher the consumer's rate. This captures the effects of idiosyncratic risks faced by the price-taking firm, e.g. the risk that the general price level will move once his own price is set in his industry. We assume that idiosyncratic risks to the firm's profits cannot be insured and that managers are incentivised by these. We can also think of there being a (constant) equity premium on shares – though this, being constant, does not enter the simulation model. The impact of a policy shock at  $t$  on the change in log productivity next quarter is estimated at  $-0.1209$ .

Given the estimates for  $\theta$  we calculate a variance decomposition, bootstrapping the model and calculating the variance in each simulated endogenous variable for each shock, as reported in Table 5. This gives some insight into the historical data from 1970–2009 given the non-rejection of the model with  $\hat{\theta}$ . The policy variable plays a significant part in generating variation in the level of all variables, particularly output, consumption, labour supply (and hence the producer cost of labour  $\tilde{w}$ ), exports and the real exchange rate. It is also responsible for generating over 18% of the variation in the quarterly growth rate of productivity. Therefore we can be sure this is distinct from an exogenous growth model; policy has an important role in the dynamics. This is because innovations in  $\tau'$  enter TFP, an I(1) process, therefore having permanent effects on the model and generating large variation in the endogenous variables.  $\tau'$  also has a direct effect on labour supply via Eq. 30.

This model has passed an extremely powerful test in which only 3% falsity leads to rejection in our Monte Carlo exercise. For a policymaker, as we have seen, this implies a very low range of parameter uncertainty and so a high degree of policy

<sup>26</sup>Note that these AR(1) coefficients are high in many cases since we use unfiltered data when we extract the structural residuals (wedges).

<sup>27</sup>The second row entry is the estimated persistence for  $e_A$ , see Eq. 37. It is relatively low since TFP itself is unit root and  $e_A$  enters the first difference of TFP (Eq. 36). Thus it is closer to the AR parameter that would be observed on the first differenced TFP series, were we to estimate  $\Delta A_t = d + b_1 \tau'_{t-1} + \rho \Delta A_{t-1} + \eta_{A,t}$ .

<sup>28</sup>The current account balance improves when the real exchange rate depreciates.

**Table 3** Structural model parameters

		Estimates
CRRA coefficient ( $C_t$ )	$\rho_1$	0.971
CRRA coefficient ( $x_t$ )	$\rho_2$	1.520
Preference weight on $C_t$	$\theta_0$	0.527
Home bias in consumption	$\omega$	0.543
Foreign equivalent of $\omega$	$\omega^F$	0.882
Import demand elasticity	$\sigma$	0.768
Elasticity of substitution ( $C_t^{d*}, C_t^{f*}$ )	$\sigma^F$	0.852
Capital equation coefficients	$\zeta_1, \zeta_2, \zeta_3, \zeta_4$	0.63, 0.35, 0.02, 0.24
$\frac{\partial z_t}{\partial \tau_t}$	$c_1$	-0.056
$\frac{\partial [d \ln A_{t+1}]}{\partial \tau_t}$	$b_1$	-0.121
Wald percentile		72.23

robustness. It also turns out that the estimated model can pass yet more powerful tests – see Appendix, Table 11 – but this is essentially otiose, given the high robustness achieved on the current test.

#### 4.4.1 Robustness - Filtering Methods and Alternative Measures of $\tau'$

The policy variable has been made stationary by removing a linear trend, on the basis that this removes the least information from the series. Removing a linear trend leaves stochastic variation which turns out to be stationary. Here we check whether the results reported above are sensitive to a change in the detrending method; we use the widely used HP filter for this check. The two different trends are plotted in Fig. 4. When the HP filtered  $\tau(1)$  variable is used when testing the structural

**Table 4** AR coefficients for structural residuals

Exogenous variable	AR coefficient	Estimated model
Shock to real interest rate	$\rho_r$	0.871
Shock to $TFP$	$\rho_A$	0.237
Shock to labour demand	$\rho_N$	0.898
Shock to capital demand	$\rho_K$	0.990
Shock to real wage	$\rho_{\bar{w}}$	0.959
Shock to export demand	$\rho_X$	0.959
Shock to import demand	$\rho_M$	0.951
Shock to $\tau$	$\rho_S$	0.968
Shock to foreign consumption demand	$\rho_{CF}$	0.918

model with the estimated coefficients reported in Table 3, we still find that the model is not rejected. The test statistic falls in the 92nd percentile of the bootstrap Wald distribution, equivalent to a p-value of 0.08.

When the  $\tau'$  series is stationarised by HP filtering rather than extracting a linear trend, the resulting innovations are smaller because the two-sided filter removes stochastic information. This explains the change in p-value for the test result. The HP filter is a different and probably worse detrending treatment of the variable (see Hamilton, 2018) which we report simply as a check on robustness to possible detrending processes. As the model is still not rejected by quite a margin, it demonstrates that the results we report do not stand or fall on the linear detrending method used to stationarise the policy variable.

**Fig. 4** Detrending methods for the policy variable

**Table 6** Key to policy variables

$\tau(1)$	Equally weighted average: LMR and top marginal tax rate on personal income
$\tau(2)$	Equally weighted average: LMR and small company tax rate on corporate profits
$\tau(3)$	LMR alone

The estimation and test results presented in Table 3 are for  $\tau(1)$ ; see Fig. 2. Here the results are checked for three measures of  $\tau'$  (Table 6). Using the Wald-minimising coefficients found above, we tested the DSGE model using  $\tau(2)$  for the policy data, finding the test statistic still well inside the non-rejection region (the Wald percentile is roughly 85). The same tests were carried out using  $\tau(3)$ ; again, the model is not rejected at 5% significance, (Wald percentile 94.41). These robustness checks show that the model's test performance is not overly sensitive to the weighting/composition of the policy index; the conclusions do not stand or fall on one component of the business environment versus another. The model passes the test for a policy driver reflecting labour market flexibility alone, and when tax indicators are added. However, the inclusion of the top marginal income tax rate with its large step changes yields a lower Wald percentile for the model and this policy component seems to have had important effects.<sup>29</sup>

## 5 Growth Episode After a Policy Reform

Impulse response functions for a one-off 1 percentage point reduction in  $\tau(1)$  illustrate the resulting growth episode, given the structural parameters in Table 3.<sup>30</sup> Although the policy shock is temporary, it affects the level of productivity permanently and shocks growth above its deterministic rate for a lengthy period (Fig. 5).<sup>31</sup> The 1 percentage point  $\tau(1)$  shock is gradually reversed over time, taking roughly ten years to die away; on average this implies that the penalty is 0.5 percentage points lower for 10 years. The log level of output is 1.6 percentage points higher than its no-shock level after 18 years. This translates to an average higher growth rate of 0.09 percentage points per annum. The growth multiplier effect of an average 0.5 percentage point  $\tau(1)$  reduction over ten years is therefore in the region of 0.17 for two

<sup>29</sup>Robustness was also carried out around the interpolation technique of  $\tau(1)$ . The conclusions are unchanged when the Denton method is applied in levels rather than differences for the labour market indicators. Where components are interpolated to quarterly frequency, robustness checks around the interpolation technique show the conclusions are similarly unaffected (constant match interpolation was checked against quadratic interpolation).

<sup>30</sup>In the exogenous  $\tau'$  process,  $\tau'_t = \rho_\tau \tau'_{t-1} + \eta_{\tau,t}$ , innovation  $\eta_{\tau,0} = 0.01$  while  $\eta_{\tau,t} = 0$  for  $t > 0$ . All other  $\eta_{i,t}$  are set to zero for all  $t$ .

<sup>31</sup>Labour supply falls initially, as the lower opportunity cost of  $z$  makes labour relatively less attractive. This causes output to fall at first, but as higher innovation in period 1 causes higher productivity next period, output rises from  $t = 2$ . Over the simulation, real wages rise to offset the income effect on labour supply from the productivity increase. Eventually  $Y$  and  $w$  converge to higher levels. Productivity growth also triggers a real business cycle upswing, not illustrated.

**Fig. 5** Impulse responses for one-off, 1 percentage point policy shock

decades.<sup>32</sup> Relating this to the UK data, Fig. 3 shows two large downward shocks around trend, the first in 1979, the second in 1988; these correspond to the 1979 budget and the 1988 budget, both of which contained sharp personal income tax rate cuts in the top band (from 0.83 to 0.6, and from 0.6 to 0.4 respectively). When the deterministic trend is extracted, these shocks are far smaller. Nevertheless, according to this model, such supply-side policy shocks would help to explain the observed reversal of UK economic decline between 1980 and the 2000s.

In conjunction with the Directed Wald test results in Section 5.1, which show the estimated model passes empirically as the explanatory process for productivity, output and a range of other macroeconomic variables, the suggestion is that UK policy over the sample period had substantial effects on economic growth and welfare.<sup>33</sup>

## 6 Conclusion

We set up an identified model in which policy reform causes short- to medium-run growth episodes, and estimate its structural parameters by indirect inference, a method attracting increasing attention in the macroeconomics literature and which is discussed further in two recent surveys in this journal (Le et al. 2016; Meenagh et al. 2019). The simulated features of this estimated model – summarised by an auxiliary model – were found through an indirect inference Wald test to be formally close to the UK data features. We interpret this as empirical evidence for the hypothesis that temporary movements in tax and regulatory policy around trend drive short-run productivity growth in our UK sample (1970–2009). Since policy shocks in the model are exogenous and uncorrelated with other shocks in the model, there is no ambiguity surrounding causation.

The tax and regulatory policy environment for this period is proxied by a weighted combination of the top marginal rate of personal income tax and a labour market regulation indicator. The estimation and test results suggest that these proxies for

<sup>32</sup>The episode is long-lasting because capital takes a long time to react fully to the rise in TFP, due to adjustment costs.

<sup>33</sup>We use the utility function to calculate welfare implications of the reform, confirming these growth gains are not achieved at the expense of welfare. However, the welfare function is basic so we do not emphasise this exercise.

‘barriers to entrepreneurship’ affected UK TFP growth negatively, consistent with the argument of Crafts (2012), Card and Freeman (2004) and Acs et al. (2009).

The Monte Carlo results we report on the statistical power of the indirect inference test as we apply it offer a sense of the robustness of these findings. The introduction of 3.5% misspecification into our structural coefficients results in rejection by the indirect inference test procedure 100% of the time. Even if only two of the structural parameter estimates are misspecified (those two being the coefficients governing the role of policy in the model), the test rejects with near certainty when those coefficients stray 50% below their true values: so for our parameter estimate of  $b_1$ , the one-period ahead impact of a one percentage point increase in the supply-side policy indicator, the estimate we obtain is -0.12 and this ‘worst-case’ power exercise furnishes a lower bound for that estimate of -0.06.

We also subject the model to the identification test of Le et al. (2017) and conclude that it is identified. The causal mechanism embedded in the DSGE model – from an increase in labour market frictions and marginal tax rates to a decrease in productivity growth – is integral to the model data generating process. Therefore if in fact (in some alternative ‘true’ model) shocks to the tax and regulatory policy index increased productivity growth rather than decreasing it, or had no perceptible effect, this model would be rejected by the test.

The implication is that for policymakers to focus exclusively on knowledge creation policy (i.e. incentivising R&D) while ignoring incentives around entrepreneurship would indeed be “seriously misguided” (Acs and Sanders 2013, p. 787). The results indicate that the creation of an environment in which businesses operate flexibly and innovatively played a supportive role in UK macroeconomic performance in 1970-2009; a less flexible environment would, based on these results, have led to a relatively worse performance in this period.

When governments must spend without building up excessive debt, the temptation is to increase marginal tax rates at the top of the income distribution; this is also a natural response to increasing social inequality.<sup>34</sup> The question of whether top marginal tax rises come with an attached growth penalty is of some relevance when considering this policy option, though of course economic growth is just one consideration in the pursuit of a social welfare optimum (albeit an important one). Our treatment of the tax structure here has abstracted from key features. Next steps would be to look at distributional effects within a heterogeneous agent framework (e.g. Coenen et al. (2008)), and to look at how revenue is raised through various distortionary tax instruments. This paper offers empirical evidence on the role of supply-side policy in past UK growth at a highly aggregated level. Future work may, by introducing more complexity into the model, look at interactions between tax policy, regulatory policy and other macroeconomic policy interventions.

**Acknowledgments** The authors would like to thank anonymous referees and the Editor of this journal for constructive suggestions on an earlier version of this paper.

<sup>34</sup>The UK government raised the top rate of income tax in 2009 from 40 to 50p, the first increase in this band for over 20 years.

## Appendix A: Model Derivations, cont.

### A.1 First order condition for $z_t$

The first order condition for  $z_t$  is:

$$\frac{dL}{dz_t} = 0 = -\beta^t \lambda_t w_t - \beta^t \lambda_t \tau_t + E_t \sum_{i=1}^{\infty} \beta^{t+i} \lambda_{t+i} \cdot \frac{d d_{t+i}}{dz_t} \tag{39}$$

At the  $(N_t, z_t)$  margin, the optimal choice of  $z_t$  trades off the impacts of a small increase  $dz_t$  on labour earnings (lower in period  $t$  due to reduced employment time), subsidy payments (higher at  $t$  in proportion to the increase in  $z_t$ ), and expected dividend income.<sup>35</sup> With substitution from 27, the first order condition can be rearranged as follows:

$$\beta^t \gamma_t C_t^{-\rho_1} w_t = \frac{a_1}{a_0 + a_1 z_t + u_t} \cdot E_t \sum_{i=1}^{\infty} \beta^{t+i} \gamma_{t+i} C_{t+i}^{-\rho_1} Y_{t+i} + \beta^t \lambda_t s_t \tag{41}$$

On the left hand side is the return on the marginal unit of  $N_t$ , the real consumer wage; on the right is the present discounted value of the expected increase in the dividend stream as a result of a marginal increase in  $z_t$ , plus time  $t$  subsidy incentives attached to R&D activity.<sup>36</sup> Substituting again from 27 for  $z_t$  yields

$$\frac{A_{t+1}}{A_t} = a_1 \cdot \frac{E_t \sum_{i=1}^{\infty} \beta^i \gamma_{t+i} C_{t+i}^{-\rho_1} Y_{t+i}}{\gamma_t C_t^{-\rho_1} (w_t + \tau_t)} \tag{42}$$

<sup>35</sup>  $\frac{dA_{t+i}}{dA_{t+i-1}} = \frac{A_{t+i}}{A_{t+i-1}}$ . Hence for  $i \geq 1$ ,

$$\frac{d A_{t+i}}{dz_t} = \frac{d A_{t+i}}{d A_{t+i-1}} \cdot \frac{d A_{t+i-1}}{d A_{t+i-2}} \dots \frac{d A_{t+2}}{d A_{t+1}} \cdot \frac{d A_{t+1}}{dz_t} = A_{t+i} \frac{A_t}{A_{t+1}} a_1 \tag{40}$$

so  $\frac{dd_{t+i}}{dz_t} = \frac{Y_{t+i}}{A_{t+i}} A_{t+i} \frac{A_t}{A_{t+1}} a_1$ . It may be objected that  $dz_t$  will enhance output directly through its effect on productivity (holding inputs fixed), and will also induce the firm to hire more capital in order to exploit its higher marginal product (similarly for labour). I assume that the effect of  $dz_t$  on the future dividend ( $d_{t+i} = \pi_{t+i}$ ) is simply its direct effect through higher TFP, on the basis that any effects on the firm's input demands are second order and can be ignored. Therefore the expected change in the dividend stream is based on forecasts for choice variables (set on other first order conditions) that are assumed independent of the agent's own activities in context of price forecasts; she anticipates only the effect of  $z_t$  on the level of output that can be produced with given inputs from  $t + 1$  onwards.

<sup>36</sup>The non-policy cost of generating new productivity via  $z_t$  is assumed to be zero. The model abstracts from a fixed or sunk cost of innovating. Moreover, time in  $z_t$  leads in a certain fashion to higher productivity, except in so far as the relationship is subject to a random shock.

Modeling the preference shock to consumption,  $\gamma_t$ , as an AR(1) stationary process such that  $\gamma_t = \rho_\gamma \gamma_{t-1} + \eta_{\gamma,t}$ , Setting  $\rho_1 \simeq 1$ , we approximate  $\frac{C_t}{Y_t}$  as a random walk, so  $E_t \frac{Y_{t+i}}{C_{t+i}} = \frac{Y_t}{C_t}$  for all  $i > 0$ .<sup>37</sup> The expression becomes

$$\frac{A_{t+1}}{A_t} = a_1 \cdot \frac{\frac{\beta \rho_\gamma}{1 - \beta \rho_\gamma} \cdot \frac{Y_t}{C_t}}{\frac{w_t}{C_t} (1 + \tau'_t)} \tag{43}$$

where  $\frac{\bar{w}_t}{w_t} \equiv \tau'_t$ . A first order Taylor expansion of the righthand side of Eq. 28 around a point where  $\tau'_t = \tau'$  gives a linear relationship between  $\frac{A_{t+1}}{A_t}$  and  $\tau'_t$  of the form

$$d \ln A_{t+1} = b_0 + b_1 \tau'_t + \varepsilon_{A,t} \tag{44}$$

where  $b_1 = -a_1 \cdot \frac{\frac{\beta \rho_\gamma}{1 - \beta \rho_\gamma} \cdot \frac{Y}{C}}{\frac{w}{C} (1 + \tau')^2}$ . Other terms in the expansion are treated as part of the error term.

### A.2 Deriving the labour supply response to policy shocks

Taking the total derivative of the time endowment in 3 gives  $dx_t = -dN_t - dz_t$ , and hence  $\frac{dx_t}{x_t} = \frac{-dN_t - dz_t}{x_t}$ . Assuming  $\bar{N} \approx \bar{x} \approx \frac{1}{2}$  in some initial steady state with approximately no  $z$  activity implies

$$\frac{dx_t}{\bar{x}} = d \ln x_t \approx -d \ln N_t - \frac{dz_t}{\bar{N}} = -d \ln N_t - 2dz_t \tag{45a}$$

Substituting into the loglinearised intratemporal condition for  $\ln w_t$  from 23 and using 45a, we obtain

$$d \ln N_t + 2c_1 d\tau'_t = -\frac{1}{\rho_2} d \ln \xi_t + \frac{1}{\rho_2} d \ln \gamma_t - \frac{\rho_1}{\rho_2} d \ln C_t + \frac{1}{\rho_2} \left[ k + d \ln \tilde{w}_t - \frac{1}{\rho} \left[ \frac{1-\omega}{\omega} \right]^\sigma d \ln \varsigma_t - \left[ \frac{1-\omega}{\omega} \right]^\sigma d \ln Q_t \right] \tag{45b}$$

Integrating this and rearranging for the log of the firm’s real unit cost of labour,  $\ln \tilde{w}_t$ , gives

$$\ln \tilde{w}_t = const_4 + \rho_2 \ln N_t + \rho_1 \ln C_t + \left[ \frac{1 - \omega}{\omega} \right]^\sigma \ln Q_t + \rho_2 2c_1 \tau'_t + e_{w,t} \tag{46}$$

where

$$e_{w,t} = -\ln \gamma_t + \ln \xi_t + \frac{1}{\rho} \left[ \frac{1 - \omega}{\omega} \right]^\sigma \ln \varsigma_t \tag{47}$$

Substituting into Eq. (28) from (27) and rearranging for  $z_t$ , then taking the derivative

with respect to  $\tau'_t$ , we find  $c_1 = -\frac{\frac{\beta \rho_\gamma}{1 - \beta \rho_\gamma} \cdot \frac{Y_t}{C_t^{\rho_1}}}{\frac{w_t}{C_t^{\rho_1}} (1 + \tau'_t)^2}$ . We could potentially calibrate  $c_1$

from this, taking appropriate values for righthand side variables. However there is flexibility around what values are appropriate in practice.

<sup>37</sup>Although in balanced growth  $\frac{C}{Y}$  is constant, in the presence of shocks the ratio will move in an unpredictable way (see Meenagh et al. 2007 for discussion). At any given point in the sample, the model is not in balanced growth, though it tends to it in the future if no further shocks are expected.

### Appendix B: The Linearised System

The linearised system of optimality conditions and constraints solved numerically is given below. Each equation is normalised on one of the endogenous variables (constants are suppressed in the errors). Variables are in natural logs except where already expressed in percentages. For clarity,  $\ln(C_t^d)^*$  and  $\ln C_t^f$  are denoted  $\ln EX_t$  and  $\ln IM_t$ .

$$r_t = \rho_1 (E_t \ln C_{t+1} - \ln C_t) + e_{r,t} \tag{48}$$

$$\ln Y_t = \alpha \ln N_t + (1 - \alpha) \ln K_t + \ln A_t \tag{49}$$

$$\ln N_t = \ln Y_t - \tilde{w}_t + e_{n,t} \tag{50}$$

$$\ln K_t = \zeta_1 \ln K_{t-1} + \zeta_2 \ln K_{t+1} + \zeta_3 \ln Y_t - \zeta_4 r_t + e_{k,t} \tag{51}$$

$$\begin{aligned} \ln C_t = & \frac{\bar{Y}}{\bar{C}} \ln Y_t - \frac{EX}{\bar{C}} \ln EX_t + \frac{IM}{\bar{C}} \ln IM_t - \frac{\bar{K}}{\bar{C}} \ln K_t \\ & + (1 - \delta - \gamma_k) \frac{\bar{K}}{\bar{C}} \ln K_{t-1} - \frac{\bar{G}}{\bar{C}} \ln G_t \end{aligned} \tag{52}$$

$$\ln \tilde{w}_t = \rho_2 \ln N_t + \rho_1 \ln C_t + \left[ \frac{1 - \omega}{\omega} \right]^\sigma \ln Q_t + \rho_2 2c_1 \tau'_t + e_{wh,t} \tag{53}$$

$$\ln w_t = \ln \tilde{w}_t - \left[ \frac{1 - \omega}{\omega} \right]^\sigma \ln Q_t + e_{w,t} \tag{54}$$

$$\ln EX_t = \ln C_t^* + \sigma^F \frac{1}{\omega} \ln Q_t + e_{X,t} \tag{55}$$

$$\ln IM_t = \ln C_t - \sigma \ln Q_t + e_{M,t} \tag{56}$$

$$\ln Q_t = E_t \ln Q_{t+1} + r_t^f - r_t \tag{57}$$

$$\Delta \hat{b}_{t+1}^f = \frac{\tilde{b}^f}{1 + g} r_t^f + \frac{\tilde{r}^f}{1 + g} \hat{b}_t^f + \left( \frac{1}{1 + g} \right) \left( \begin{aligned} & \frac{EX}{\bar{Y}} \ln EX_t - \frac{EX}{\bar{Y}} \frac{1}{\omega} \ln Q_t \\ & - \frac{IM}{\bar{Y}} \ln IM_t \end{aligned} \right) \tag{58}$$

$$\ln A_t = \ln A_{t-1} + b_1 \tau'_{t-1} + e_{A,t} \tag{59}$$

$$\ln C_t^* = \rho_{C^*} \ln C_{t-1}^* + \eta_{C^*,t} \tag{60}$$

$$\ln G_t = \rho_G \ln G_{t-1} + \eta_{G,t} \tag{61}$$

$$r_t^f = \rho_{rf} r_{t-1}^f + \eta_{rf,t} \tag{62}$$

$$\tau'_t = \rho_\tau \tau'_{t-1} + \eta_{\tau,t} \tag{63}$$

### Appendix C: Data Appendix

Table 7 contains all definitions and sources of data used in the study, as well as a symbol key. Most UK data are sourced from the UK Office of National Statistics (ONS); others from International Monetary Fund (IMF), Bank of England (BoE), UK Revenue and Customs (HMRC) and Organisation for Economic Cooperation and Development (OECD). Labour Market Indicators are taken from the Fraser Institute Economic Freedom Project, which sources them from the World Economic

**Table 7** Data description

Symbol	Variable	Definition and description	Source
$Y$	Output	Gross domestic product; constant prices.	ONS
$N$	Labour	Ratio of total employment to 16+ working population <sup>1</sup>	ONS
$K$	Capital stock	Calculated from investment data (I) using Eq. 21	(na)
$I$	Investment	Gross fixed capital formation + changes in inventories	ONS
$C$	Consumption	Household final consumption expenditure by households	ONS
$A$	Total factor productivity	Calculated as the Solow Residual in Eq. 18	(na)
$G$	Government consumption	General government, final consumption expenditure	ONS
$IM$	Imports	UK imports of goods and services	ONS
$EX$	Exports	UK exports of goods and services	ONS
$Q$	Terms of trade	Calculated from $\frac{E \cdot P_F}{P}$	(na)
$E$	Exchange rate	Inverse of Sterling effective exchange rate	ONS
$P_F$	Foreign price level	Weighted av. of CPI in US (0.6), Germany (0.19) & Japan (0.21)	IMF
$P$	Domestic general price level	Ratio, nominal to real consumption	ONS
$b_F$	Net foreign assets	Ratio of nominal net foreign assets (NFA) to nominal GDP <sup>2</sup>	ONS
$w$	Consumer real wage	Average earnings index <sup>3</sup> divided by $P_t$	ONS
$\tilde{w}$	Unit cost of labour	Average earnings index <sup>3</sup> divided by GDP deflator	ONS
$r$	Real interest rate, domestic	Nominal interest rate minus one period ahead inflation.	(na)
$R$	Nominal interest rate, domestic	UK 3 month treasury bill yield	BoE
$r_F$	Real interest rate, foreign	$R_F$ minus one-period ahead inflation (year-on-year change in $P_F$ )	(na)
$R_F$	Nominal interest rate, foreign	Weighted av., 3-month discount rates, US, Germany & Japan <sup>4</sup>	IMF
$C_F$	Foreign consumption demand	World exports in goods and services	IMF
$\tau(1)$	Tax & regulatory environment	Equally weighted av., LMR and top marginal income tax	HMRC
$\tau(2)$	Tax & regulatory environment	Equally weighted av., LMR and corporation tax (SME rate)	HMRC
$\tau(3)$	Labour market regulation(LMR)	Equally weighted av., CCB and MCH (interpolated using TUM)	Various
$TUM$	Trade union membership rate	Trade union membership over working pop (16+).	ONS

Forum's Global Competitiveness Report (GCR) and the World Bank (WB). All data seasonally adjusted and in constant prices unless specified otherwise.

### C.1 Data for Policy Indicator

UK data on  $\tau'_t$  reflects regulation and tax. On regulation, the focus (due to data range and availability) is on the labour market. Two components are selected from the labour market sub-section of the Economic Freedom (EF) indicators compiled by the Fraser Institute: the Centralized Collective Bargaining (CCB) index and Mandated Cost of Hiring (MCH) index. Of the labour market measures, these two components span the longest time-frame.

The original data source for CCB is World Economic Forum's Global Competitiveness Report (various issues). Survey participants answer the following question: "Wages in your country are set by a centralized bargaining process (= 1) or up to each individual company (= 7)". The Fraser Institute converts these scores onto a [0,10] interval. MCH is constructed from World Bank Doing Business data, reflecting "the cost of all social security and payroll taxes and the cost of other mandated benefits including those for retirement, sickness, health care, maternity leave, family allowance, and paid vacations and holidays associated with hiring an employee" (Fraser Institute 2009). These costs are also converted to a [0,10] interval; zero represents a hiring process with high regulatory burden.<sup>38</sup> Labour market flexibility increases with both indices in their raw form. These [0,10] scores are scaled to a [0,1] interval before being interpolated as follows.

UK trade union membership (TUM) data is available annually from the late 1800s. TUM data for 1970 to 2009 is made quarterly by quadratic three-point interpolation (estimated values average to annual values), then divided by total employment (16+) to give a quarterly union membership rate on a [0,1] scale. This is inverted and used to interpolate both the CCB and MCH series via the Denton proportionate variant adjustment method (Denton 1971). The unionisation rate is used to interpolate CCB and MCH on theoretical grounds; we expect union membership to be greater when bargaining power of unions is higher. Equally, increased protection of worker benefits should be correlated with a strong worker voice represented by unions.<sup>39</sup> The correlations in the data bear this out (Table 8).

The resulting quarterly series for CCB and MCH incorporate information from the unionisation rate.<sup>40</sup> The interpolated series are inverted to represent a penalty rate; a higher value indicates a more hostile business environment. They are plotted in Fig. 6

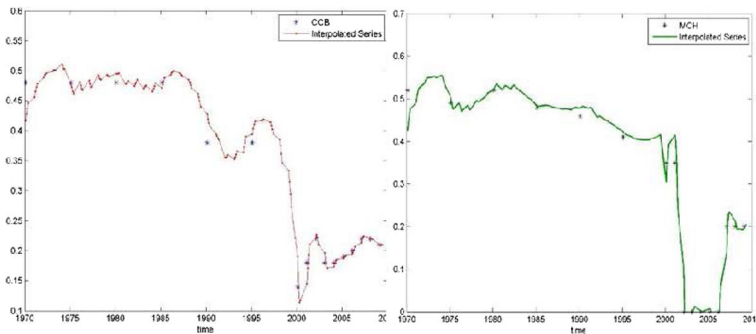

<sup>38</sup>The formula used to calculate the zero-to-10 ratings was:  $(V_{\max} - V_i) / (V_{\max} - V_{\min})$  multiplied by 10.  $V_i$  represents the hiring cost (measured as a percentage of salary). The values for  $V_{\max}$  and  $V_{\min}$  were set at 33% (1.5 standard deviations above average) and 0%, respectively. Countries with values outside of the  $V_{\max}$  and  $V_{\min}$  range received ratings of either zero or 10, accordingly". Fraser Institute (2009).

<sup>39</sup>Alternative theories predict a negative correlation between MCH and union membership (the idea that unions are only needed when the government fails to represent workers' interests directly) but the data indicate a positive correlation.

<sup>40</sup>The interpolation is carried out for both level and first differences of  $y/x$ , where  $y$  is the low frequency series and  $x$  the higher frequency series (the union membership rate); the resulting series are very similar but first differences are smoother. We use the first difference output.

**Table 8** Correlations: Fraser Institute Labour Market Indicators CCB and MCH, and Trade Union Membership rate, inverted (TUM inv)

	CCB	MCH
MCH	0.797	1.000
TUM (inv)	0.899	0.764

**Fig. 6** Inverted Fraser Institute indices. Left panel: Centralized Collective Bargaining (CCB) score; original points and interpolated series. Right panel: Marginal Cost of Hiring (MCH).**Table 9** Correlations: OECD product market regulation indicator (Network Industries), Fraser Institute indicators (CCB and MCH), and trade union membership

	PMR(inv)
CCB	0.947
MCH	0.800
TUM(inv)	0.962

against the scatter of low frequency data points (scaled to [0,1] and inverted). Neither interpolated series strays far from the original score.

The interpolated, inverted CCB and MCH indicators are equally weighted together to give the ‘Labour Market Regulation’ indicator (LMR) of labour market inefficiency (Fig. 2).<sup>41</sup> Other types of regulation are not incorporated into  $\tau'_i$  in this study, since measures spanning the sample period are largely unavailable. However, the high positive correlation between the Fraser Institute CCB and MCH measures and the OECD indicator of Product Market Regulation is interesting (Table 9). The LMR indicator may not be a bad proxy for product market entry regulation in the UK.

<sup>41</sup>A fuller measure would reflect employment protection legislation including firing costs (see e.g. Botero et al. 2004), but data availability is a constraint. Correlations of our LMR indicators with (highly time-invariant) OECD EPL measures from 1985 for the UK are actually negative; our indicators do not fully capture the increases in dismissal regulation over the period and thus may slightly overstate the extent to which the UK labour market is ‘deregulated’; however, the strong decline of collective bargaining and union power over the period represents the removal of significant labour market friction.

The second part of the index for  $\tau_t'$  reflects the tax environment. The top marginal income tax rate is used for  $\tau(1)$  (see main text).

### Appendix D: Auxiliary Model

The full linearised structural model, comprising a  $p \times 1$  vector of endogenous variables  $y_t$ , a  $r \times 1$  vector of expected future endogenous variables  $E_t y_{t+1}$ , a  $q \times 1$  vector of non-stationary variables  $x_t$  and a vector of i.i.d. errors  $e_t$ , can be written in the general form

$$A(L)y_t = BE_t y_{t+1} + C(L)x_t + D(L)e_t \tag{64}$$

$$\Delta x_t = a(L)\Delta x_{t-1} + d + b(L)z_{t-1} + c(L)\epsilon_t \tag{65}$$

$x_t$  is a vector of unit root processes, elements of which may have a systematic dependency on the lag of  $z_t$ , itself a stationary exogenous variable (this variable is subsumed into the shock below).  $\epsilon_t$  is an i.i.d., zero mean error vector. All polynomials in the lag operator have roots outside the unit circle. Since  $y_t$  is linearly dependent on  $x_t$  it is also non-stationary. The general solution to this system is of the form

$$y_t = G(L)y_{t-1} + H(L)x_t + f + M(L)e_t + N(L)\epsilon_t \tag{66}$$

**Table 10** Correlation coefficients for tax and regulatory components of composite index. Correlations are with the inverted, interpolated Fraser index scores for CCB and MCH (higher score indicates higher regulation)

	CCB	MCH
Top marginal income tax rates	0.786	0.623
Corporate tax (SME rate)	0.868	0.700

**Table 11** Indirect Inference test results for auxiliary VARX(1), various endogenous variables

Auxiliary model	(11)	(12)	(13)	(14)	(15)
Endogenous	Y, A, X	Y, A, M	Y, A, M, X	Y, A, K, C	Y, A, Q, N
Wald percentile	96.12	86.40	98.71	94.26	95.12
Auxiliary model	(16)	(17)	(18)	(19)	(20)
Endogenous	Y, A, M, Q	Y,A,M,Q,r	Y, A, C, M	Y, A, w	Y, A, $\tilde{w}$
Wald percentile	93.38	95.25	99.1	97.28	98.60

where  $f$  is a vector of constants. Under the null hypothesis of the model, the equilibrium solution for the endogenous variables is the set of cointegrating relationships (where  $\Pi$  is  $p \times p$ )<sup>42</sup>:

$$y_t = [I - G(1)]^{-1}[H(1)x_t + f] \tag{67}$$

$$= \Pi x_t + g \tag{68}$$

though in the short run  $y_t$  is also a function of deviations from this equilibrium (the error correction term  $\eta_t$ ):

$$y_t - (\Pi x_t + g) = \eta_t \tag{69}$$

In the long run, the level of the endogenous variables is a function of the level of the unit root variables, which are in turn functions of all past shocks.

$$\bar{y}_t = \Pi \bar{x}_t + g \tag{70}$$

$$\bar{x}_t = [1 - a(1)]^{-1}[dt + c(1)\xi_t] \tag{71}$$

$$\xi_t = \sum_{s=0}^{t-1} \varepsilon_{t-s} \tag{72}$$

Hence the long-run behaviour of  $\bar{x}_t$  can be decomposed into a deterministic trend part  $\bar{x}_t^D = [1 - a(1)]^{-1}dt$  and a stochastic part  $\bar{x}_t^S = [1 - a(1)]^{-1}c(1)\xi_t$ , and the long run behaviour of the endogenous variables is dependent on both parts. Hence the endogenous variables consist of this trend and of deviations from it; one could therefore write the solution as this trend plus a VARMA in deviations from it. An alternative formulation is as a cointegrated VECM with a mixed moving average error term

$$\Delta y_t = -[I - G(1)](y_{t-1} - \Pi x_{t-1}) + P(L)\Delta y_{t-1} + Q(L)\Delta x_t + f + \omega_t \tag{73}$$

$$\omega_t = M(L)e_t + N(L)\varepsilon_t \tag{74}$$

which can be approximated as

$$\Delta y_t = -K[y_{t-1} - \Pi x_{t-1}] + R(L)\Delta y_{t-1} + S(L)\Delta x_t + h + \zeta_t \tag{75}$$

or equivalently, since  $\bar{y}_{t-1} - \Pi \bar{x}_{t-1} - g = 0$ ,

$$\Delta y_t = -K[(y_{t-1} - \bar{y}_{t-1}) - \Pi(x_{t-1} - \bar{x}_{t-1})] + R(L)\Delta y_{t-1} + S(L)\Delta x_t + m + \zeta_t \tag{76}$$

considering  $\zeta_t$  to be i.i.d. with zero mean. Rewriting Eq. 75 as a levels VARX(1) we get

$$y_t = [I - K]y_{t-1} + K\Pi x_{t-1} + n + \phi t + q_t \tag{77}$$

where the error  $q_t$  now contains the suppressed lagged difference regressors, and the time trend is included to pick up the deterministic trend in  $\bar{x}_t$  which affects both the endogenous and exogenous variables.  $x_{t-1}$  contains unit root variables which must be present to control for the impact of past shocks on the long run path of both  $x$  and  $y$ . This VARX(1) approximation to the reduced form of the model is the basis for the unrestricted auxiliary model used throughout the estimation.

<sup>42</sup>In fact the matrix  $\Pi$  is found when we solve for the terminal conditions on the model, which constrain the expectations to be consistent with the structural model's long run equilibrium.
