Mechanism of Photocatalytic Reduction of CO$_2$ by Ag$_3$PO$_4$(111)/g-C$_3$N$_4$
Nanocomposite: A First Principles Study

Abstract

Density functional Theory (DFT) calculations have been performed to investigate the electronic structure and photocatalytic activity of a hybrid Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ structure. Due to Ag(d) and O(p) states forming the upper part of the valence band and C(p), N(p) and Ag(s) the lower part of the conduction band, the band gap of the hybrid material is reduced from 2.75 eV for Ag$_3$PO$_4$(111) and 3.13 eV for monolayer of g-C$_3$N$_4$ to about 2.52 eV, enhancing the photocatalytic activity of the Ag$_3$PO$_4$(111) surface and g-C$_3$N$_4$ sheet in the visible region. We have also investigated possible reaction pathways for photocatalytic CO$_2$ reduction on the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ nanocomposite to determine the most favored adsorption geometries of reaction intermediates and the related reaction energies. For CO$_2$ reduction, our findings demonstrate that the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ heterostructure thermodynamically exhibits a higher selectivity towards CH$_4$ production than that of CH$_3$OH. The CO$_2$ reduction process takes place through either HCOOH* or HOCHO* as an intermediate species, where the highest exothermic reaction energy of -2.826 eV belongs to the hydrogenation of t-COOH* to HCOOH* and the lowest reaction energy of -0.182 eV for hydrogenations of CH$_2$O* to CH$_2$OH* and HCO* to c-HCOH*. Our results from charge density difference calculations of the Ag$_3$PO$_4$(111)/Ag/g-C$_3$N$_4$ revealed that the charge transfer between the Ag$_3$PO$_4$(111) slab and g-C$_3$N$_4$ monolayer occurs through mediation of atomic Ag, thus
proposing a Z-scheme mechanism. Moreover, a smaller band gap energy of 0.73 eV is calculated for this ternary nanocomposite due to the mid-gap states of the atomic Ag at the interface. These results provide in depth understanding of the reaction mechanism in the reduction and conversion of CO\textsubscript{2} to useful chemicals via an Ag\textsubscript{3}PO\textsubscript{4} and g-C\textsubscript{3}N\textsubscript{4}-based nanocomposite photocatalyst under visible light.

1. Introduction

Population growth and industrial development are among major factors limiting availability of dwindling fossil fuel resources. In addition, as a result of their combustion, CO\textsubscript{2} emissions into the environment and the resulting greenhouse effect have led to significant concerns about climate change.\textsuperscript{1} Therefore, conversion of CO\textsubscript{2} to valued products is an important issue in both energy and environmental global concerns. These questions have led to extensive research in CO\textsubscript{2} conversion into useful alternative hydrocarbon products, including methanol (CH\textsubscript{3}OH), methane (CH\textsubscript{4}), formic acid (HCOOH), and formaldehyde (CH\textsubscript{2}O). A number of strategies are considered to address this issue such as photocatalytic reduction of CO\textsubscript{2} using appropriate composite semiconductor photocatalysts.\textsuperscript{2-3}

Several photocatalysts have been examined for their potential to catalyze CO\textsubscript{2} conversion reactions, through decreasing their charge carrier recombination rate or via better visible-light harvesting, leading to improved photocatalytic efficiency. Due to the efficient separation of photo-excited electrons and holes, silver orthophosphate (Ag\textsubscript{3}PO\textsubscript{4}) possesses excellent photocatalytic properties. Recent studies have shown high photo-oxidative capabilities for O\textsubscript{2} evolution from water splitting,\textsuperscript{4} as well as decolorization of organic dyes\textsuperscript{5} over Ag\textsubscript{3}PO\textsubscript{4}. The major problem for practical applications of Ag\textsubscript{3}PO\textsubscript{4} is its low structural stability. Several studies have been carried out to improve the stability and thus the photocatalytic activity of Ag\textsubscript{3}PO\textsubscript{4} by coupling it with other
semiconductors, such as $\text{TiO}_2^6$, $\text{ZnO}^7$, $\text{Bi}_2\text{WO}_6^8$, $\text{BiOI}^9$, oxidized graphene$^{10}$, reduced graphite oxide$^{11}$, and carbon quantum dots$^{12}$. Moreover, plasmonic effects induced by Ag nanoparticles generated by $\text{Ag}_3\text{PO}_4$, during its coupling with other semiconductor under visible light irradiation, leads to improved charge separation, resulting in a high photocatalytic activity. A comprehensive review on coupling of several 2D materials with a number of semiconductor oxides and the role of interfaces in photocatalytic reactions has been published recently$^{13}$.

Graphitic carbon nitride (g-$\text{C}_3\text{N}_4$) has been reported as a novel, metal-free layered semiconductor and visible-light-driven photocatalyst for the degradation of organic pollutants$^{14}$ and hydrogen evolution from water splitting$^{15}$ as well as $\text{CO}_2$ reduction$^{16}$. Due to its medium band gap energy ($\sim2.7$ eV), low specific surface area and fast charge recombination rate, it is widely accepted that g-$\text{C}_3\text{N}_4$ must be coupled with other photocatalysts to enhance its photocatalytic activity, including $\text{TiO}_2^{17}$, $\text{CdS}^{18}$, $\text{SiO}_2^{19}$, $\text{Al}_2\text{O}_3^{20}$ or $\text{Ag}_3\text{VO}_4^{21}$. In addition, the photocatalytic activity of g-$\text{C}_3\text{N}_4$ can be also improved by doping it with other elements, e.g. $\text{B/P}^{22}$, $\text{Na}^{23}$, $\text{K}^{23}$ or $\text{Au}^{24}$.

A few studies have focused on combining $\text{Ag}_3\text{PO}_4$ with g-$\text{C}_3\text{N}_4$ to enhance the photocatalytic activity. For example, a higher photocatalytic activity in water oxidation and oxygen production for the $\text{Ag}_3\text{PO}_4$/g-$\text{C}_3\text{N}_4$ nanocomposite was found with a Z-scheme charge transfer mechanism, where Ag atoms generated by $\text{Ag}_3\text{PO}_4$ act as a cross-linking bridge the interface of the $\text{Ag}_3\text{PO}_4$ and g-$\text{C}_3\text{N}_4$.$^{25-26}$ Other studies have also demonstrated enhanced photocatalytic performance of the $\text{Ag}_3\text{PO}_4$/g-$\text{C}_3\text{N}_4$ system towards decomposition of Methyl Orange$^{27}$, phenol$^{28}$, bisphenol A$^{28}$, Rhodamine B$^{29}$, ciprofloxacin$^{30}$, and the oxidation of ethylene$^{31}$ under visible light. A higher photocatalytic performance of combined $\text{Ag}_3\text{PO}_4$ and g-$\text{C}_3\text{N}_4$ towards degradation of methylene blue$^{30, 32-33}$ and removal of $\text{NO}_3^{33}$ was also studied, where the enhancement was ascribed to the efficient separation of electron-hole pairs through a Z-scheme charge transfer mechanism of the
Ag₃PO₄/Ag/g-C₃N₄. Zhang et al.³⁴ have reported improvement of the stability and light absorption ability of the Ag₃PO₄/g-C₃N₄ compared to pure Ag₃PO₄, where they measured enhancement in photodegradation of diclofenac for the hybrid system. In another study, the Ag₃PO₄/g-C₃N₄ nanocomposite was synthesized by Zhou et al.³⁵ They showed a higher photocatalytic activity towards the degradation of sulfamethoxazole through a Z-scheme charge transfer mechanism. Yiming He et al.³⁶ have synthesized the Ag₃PO₄/g-C₃N₄ heterojunction using a simple in situ deposition method, observing enhanced photocatalytic CO₂ reduction, where atomic Ag acted as the recombination center for electrons and holes by a Z-scheme charge carrier pathway. However, despite these promising studies, to the best of our knowledge, no computational study has as yet been carried out on the Ag₃PO₄/g-C₃N₄ hybrid system. In this investigation, geometrical and electronic properties of the Ag₃PO₄(111)/g-C₃N₄ heterojunction photocatalyst for CO₂ photo-reduction have been studied using density functional theory (DFT) calculations, to gain understanding of the charge transfer mechanism at the interface. As shown in theoretical and experimental studies, control of surface structure is an important requirement for the improvement of the photocatalytic activity, where it is widely accepted that a high surface energy – indicating a less stable and more reactive surface - is beneficial to improve the photocatalytic efficiency of the facets³³, 37-39. It is well known that {111} facet of the Ag₃PO₄ is the least stable and most reactive facet with its higher surface energy among the {111}, {110} and {100} facets³³, 37-38. The literature also indicates that the exposed {111} facets show the highest photocatalytic activity under visible light irradiation among the lowest-index {111}, {110} and {100} facets, due to the larger band gap of the Ag₃PO₄ {111} surface which suppresses the recombination of electron–hole pairs, in addition to the photo-generation of electrons with higher
energy and activity in the conduction band of \{111\} surfaces than those on the other low-index surfaces.\textsuperscript{33}

Furthermore, a hybrid g-C\textsubscript{3}N\textsubscript{4}/Ag\textsubscript{3}PO\textsubscript{4} material with reactive \{111\} facets is expected to display excellent photocatalytic performance under visible light irradiation, as confirmed by experiment.\textsuperscript{33, 38} Thus in this study, the Ag\textsubscript{3}PO\textsubscript{4}(111) was chosen to be coupled with a monolayer of g-C\textsubscript{3}N\textsubscript{4}, where a DFT approach was used to define the effect of metallic Ag as a recombination center on the electronic properties of the hybrid Ag\textsubscript{3}PO\textsubscript{4}(111)/g-C\textsubscript{3}N\textsubscript{4} photocatalyst in the CO\textsubscript{2} reduction process.

2. Computational Details

We have performed electronic structure calculations using DFT as implemented in the Vienna Ab initio Simulation Package (VASP)\textsuperscript{40-41}. The total energy calculations have been performed using the Perdew-Burke-Ernzerhof (PBE)\textsuperscript{42} form of the generalized gradient approximation (GGA) with the projector augmented wave (PAW) method\textsuperscript{43-45}. As has been shown in other studies\textsuperscript{45}, inclusion of the long-range Van der Waals (vdW) forces improves the energy description of each system, and we have therefore employed the DFT-D3, method of Grimme as implemented in VASP\textsuperscript{46}.

In this study, the Ag\textsubscript{3}PO\textsubscript{4}(111)/g-C\textsubscript{3}N\textsubscript{4} nanocomposite was created by adding a monolayer of g-C\textsubscript{3}N\textsubscript{4} on top of a Ag\textsubscript{3}PO\textsubscript{4}(111) slab. Since experiment has shown that Ag\textsuperscript{+} generated by Ag\textsubscript{3}PO\textsubscript{4} is reduced to Ag atom and the composite consists of Ag\textsubscript{3}PO\textsubscript{4}, Ag and g-C\textsubscript{3}N\textsubscript{4}, we investigated the effect of atomic Ag in the composite on the photocatalytic activity of the Ag\textsubscript{3}PO\textsubscript{4}(111)/g-C\textsubscript{3}N\textsubscript{4} hetero-structure. To create the Ag\textsubscript{3}PO\textsubscript{4}(111)/Ag/g-C\textsubscript{3}N\textsubscript{4} composite, we first added an Ag ad-atom to the g-C\textsubscript{3}N\textsubscript{4} and allowed this structure to relax. We next positioned this material with the Ag side on top of the Ag\textsubscript{3}PO\textsubscript{4}(111) slab and optimized the entire slab. The hybrid photocatalyst structure
has a hexagonal super cell with dimension of 8.287Å and a lattice mismatch of nearly 6% (see Figure 1).

The electron wave functions were expanded using plane waves with a cutoff energy of 600 eV for g-C$_3$N$_4$ bulk and monolayer and 450 eV for Ag$_3$PO$_4$ bulk, Ag$_3$PO$_4$(111), Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ and Ag$_3$PO$_4$(111)/Ag/g-C$_3$N$_4$ structures, which high values ensured that no Pulay stresses occurred within the cells during relaxation. The convergence criteria for the residual force and energy on each atom during structure relaxations were set to 0.01 eV/Å and $10^{-5}$ eV, respectively. A vacuum space was set more than 20 Å that is introduced to avoid interactions between periodic images.

Hybrid DFT, which is obtained by mixing in a fixed amount of Hartree–Fock exchange, was used to get exact electronic properties.$^{47}$ PBE$^0$ and Heyd-Scuseria-Ernzerhof (HSE0)$^{49}$ formalisms were applied for Ag$_3$PO$_4$(111) and g-C$_3$N$_4$, respectively to obtain the correct band gap in line with In addition, PBE0 used for the hybrid Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ and ternary Ag$_3$PO$_4$(111)/Ag/g-C$_3$N$_4$ nanocomposites, because this hybrid functional leads to band gaps in the visible light irradiation area that matches other studies.$^{25-36}$ A 6×6×1 gamma grid of k-points was used to sample the Brillouin zone for monolayer g-C$_3$N$_4$ and a 4×4×1 grid for the Ag$_3$PO$_4$(111) slab, Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ and Ag$_3$PO$_4$(111)/Ag/g-C$_3$N$_4$ hybrid structures. The g-C$_3$N$_4$ monolayer modeled by a (3 × 3) supercell, which is equivalent to a 3 × 3 supercell containing 21 atoms and three primitive unit cells as has been used in the study by Algara et al.$^{55}$ sits on a 1 × 1 Ag$_3$PO$_4$(111) surface slab containing 80 atoms and six 4×3 units, including four bottom 4×3 units fixed at bulk position.

3. Results and Discussion

3.1. Geometrical Structure
We have investigated the Ag$_3$PO$_4$ bulk, Ag$_3$PO$_4$(111) surface, g-C$_3$N$_4$ bulk and g-C$_3$N$_4$ monolayer. The optimized cell parameters were $a = b = 6.012$ Å for Ag$_3$PO$_4$ bulk and $a = b = 4.746$ Å for a monolayer of g-C$_3$N$_4$, which are both in good agreement with measured experimental values ($6.004$ Å $^{56}$ for Ag$_3$PO$_4$ bulk and $4.742$ Å $^{57}$ for g-C$_3$N$_4$ monolayer) and previous theoretical values ($6.010$ Å $^{58}$ for Ag$_3$PO$_4$ bulk and $4.774$ Å $^{50}$ for g-C$_3$N$_4$ monolayer).

The thermodynamic stability of the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ nanocomposites can be described by the interface adhesion energy using the following equation:

$$ E_{ad} = E_{total} - E_{Ag}_3PO_4(111) - E_{g-C}_3N_4 $$

where $E_{total}$ represents the total energy of the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ hybrid structure, $E_{Ag}_3PO_4(111)$ is the energy of the Ag$_3$PO$_4$(111) surface, and $E_{g-C}_3N_4$ is the energy of the g-C$_3$N$_4$ monolayer, respectively. The $E_{ad}$ is calculated at about -1.90 eV for the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ hybrid structure. The negative sign denotes that the hybrid structure is stable thermodynamically with respect to the individual component materials and that strong interactions exists between the g-C$_3$N$_4$ monolayer and Ag$_3$PO$_4$(111) surface.

The top and side views of the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ and Ag$_3$PO$_4$(111)/Ag/g-C$_3$N$_4$ interface models used in our calculations, after geometry optimization, are shown in Fig. 1, indicating more interaction at the interface of the ternary composite. There is a shorter distance between g-C$_3$N$_4$ layer and Ag$_3$PO$_4$(111) surface in the Ag$_3$PO$_4$/Ag/g-C$_3$N$_4$ and a more distorted g-C$_3$N$_4$ structure (Fig. 1b), due to the presence of atomic Ag at the interface.

To investigate the charge transfer mechanism between g-C$_3$N$_4$ and the Ag$_3$PO$_4$(111) surface, the differential charge densities are calculated and plotted in Fig. 2. It can be seen that more charge transfer occurs between the Ag atom and the g-C$_3$N$_4$ monolayer, leading to more interaction at the
interface; experiment has already confirmed that Ag acts as a recombination center at the interface, leading to improvement in the photocatalytic activity\textsuperscript{36}.

3.2. Band Structure and Density of States

To understand the nature of the interaction between g-C\textsubscript{3}N\textsubscript{4} monolayer and Ag\textsubscript{3}PO\textsubscript{4}(111) surface, band structure calculations of the g-C\textsubscript{3}N\textsubscript{4} monolayer, Ag\textsubscript{3}PO\textsubscript{4}(111) surface, and Ag\textsubscript{3}PO\textsubscript{4}(111)/g-C\textsubscript{3}N\textsubscript{4} hybrid structure, as well as the g-C\textsubscript{3}N\textsubscript{4} and Ag\textsubscript{3}PO\textsubscript{4} bulk, were carried out and the results are shown in Figure 3. The calculated results with PBE0 hybrid functional show that Ag\textsubscript{3}PO\textsubscript{4} bulk has an indirect band gap of 2.47 eV, with the valence band maximum (VBM) located at M point and the conduction band minimum (CBM) placed at the $\Gamma$ point (Fig. 3a), which agrees well with other experimental\textsuperscript{5} and theoretical studies\textsuperscript{51}. The Ag\textsubscript{3}PO\textsubscript{4}(111) surface has a direct band gap of 2.75 eV, shown in Fig. 3b, which matches the theoretical result reported by Zheng et al.\textsuperscript{12}. In addition, the direct band gaps for g-C\textsubscript{3}N\textsubscript{4} bulk and its monolayer, calculated with the HSE0 hybrid functional, are 2.75 and 3.13 eV at X and Y high symmetry points, (Fig. 3c and 3d), respectively. These results are also consistent with recent experimental and calculated findings\textsuperscript{50, 52-53}. The calculated band structure of the hybrid Ag\textsubscript{3}PO\textsubscript{4}(111)/g-C\textsubscript{3}N\textsubscript{4} system, with an indirect band gap as large as 2.52 eV, is illustrated in Fig. 3e. It should be noted that the obtained smaller band gap of the hybrid structure can dramatically enhance the photocatalytic performance of g-C\textsubscript{3}N\textsubscript{4} monolayers under visible irradiation.

To further understand the electronic structure at the interface of the Ag\textsubscript{3}PO\textsubscript{4}(111)/g-C\textsubscript{3}N\textsubscript{4} hybrid system, the total DOS (TDOS) and its projected DOS (PDOS) were also calculated and the results are shown in Figure 4. According to Fig. 4a, while the CBM of the Ag\textsubscript{3}PO\textsubscript{4}(111)/g-C\textsubscript{3}N\textsubscript{4} heterostructure mainly originates from the atomic orbitals of the g-C\textsubscript{3}N\textsubscript{4} sheet, the VBM is dominated by the Ag\textsubscript{3}PO\textsubscript{4}(111) states. The VBM of the hetero-structure is mainly occupied by the O(p) and
Ag(d) orbitals of the Ag$_3$PO$_4$(111), where they are higher than those of g-C$_3$N$_4$ (Fig. 4b). Moreover, Fig. 4c indicates that the CBM of the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ is composed of the C(p) and N(p) orbitals of g-C$_3$N$_4$ monolayer, with the Ag(s) and O(p) orbitals of the Ag$_3$PO$_4$(111) also occupying some states of CBM.

To examine the effect of atomic Ag on the electronic properties of the interface, we have further investigated the total density of states and band structure of the Ag$_3$PO$_4$/Ag/g-C$_3$N$_4$ composite, as shown in Fig. 5. The presence of atomic Ag at the interface between the Ag$_3$PO$_4$(111) surface and g-C$_3$N$_4$ monolayer is confirmed by the states in the mid-gap of the Ag$_3$PO$_4$/Ag/g-C$_3$N$_4$ hybrid structure near the VBM, where they act as a recombination charge center (Fig. 5a). These states has decreased the band gap to 0.73 eV where the VBM is located at the T point, and CBM appears at the $\Gamma$ point, resulting in an indirect band gap semiconductor (Fig. 5b). To gain better understanding of the mid-gap states, we investigated the PDOS of the Ag$_3$PO$_4$/Ag/g-C$_3$N$_4$ structure, as shown in Fig. 6. Our calculations reveal that the main contributors to the mid-gap states are the atomic Ag at the interface, as well as the O atoms in the top layer of Ag$_3$PO$_4$ and the closest N and C atoms of the g-C$_3$N$_4$ sheet. These results confirm that the Ag atoms are generated via the reduction of ionic Ag of the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ composite; their presence has recently been confirmed by experiment.$^{36}$ The above findings indicate that the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ system is a Z-scheme type photo-catalyst, which has already been reported by experiment.$^{36, 59}$ It is worth noting that the formation of Ag atoms in the composite, acting as charge carrier recombination centers, thus promotes the separation efficiency of electron-hole pairs, leading to higher photo-activity of Ag$_3$PO$_4$/g-C$_3$N$_4$$^{60, 61}$. In general, The VBM and CBM edge positions of a semiconductor can be calculated according to the following equations;
where $\chi$ is the absolute electronegativity of the semiconductor, which for g-C$_3$N$_4$ and Ag$_3$PO$_4$ are 4.73 and 5.96 eV, respectively. $E_g$ represents the energy of free electrons in the normal hydrogen electrode (NHE) (about 4.5 eV), $E_{\text{g}}$ is the band gap energy of the semiconductor. The calculated band gaps for the g-C$_3$N$_4$ monolayer, Ag$_3$PO$_4$ (111) surface and Ag$_3$PO$_4$/g-C$_3$N$_4$ hybrid composite are 3.13, 2.75 and 2.52 eV, respectively. According to the above equations, the positions of the CB and VB of g-C$_3$N$_4$ are then -1.34 and 1.80 eV versus NHE, as shown in Fig. 7, which the obtained values are consistent with other studies. As displayed in Fig. 7, the calculated CB and VB for the Ag$_3$PO$_4$(111) surface are 0.09 and 2.84 eV, versus NHE, respectively.

Ag$_3$PO$_4$ (111) with a band gap of 2.75 eV can absorb visible light, but its CB edge is located at 0.09 V, which is lower than the potential required for reduction of CO$_2$ to hydrocarbon products like CH$_3$OH, CH$_4$, HCOOH and CH$_2$O, (see Fig. 7). In contrast, the CB of g-C$_3$N$_4$ is above the CO$_2$ reduction reaction potentials and the photo-generated electrons can thus easily reduce CO$_2$ to these products (Fig. 7). As such, the hybrid Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ system can catalyze the CO$_2$ reduction only if it follows the Z-scheme mechanism, which could happen through the presence of atomic Ag as the recombination center for the photo-generated electrons in the CB of Ag$_3$PO$_4$(111) and holes in the VB of the g-C$_3$N$_4$ sheet, as displayed in Fig. 7. Considering such a mechanism, the photo-excited electrons in the CB of g-C$_3$N$_4$ can reduce CO$_2$, leading to excellent photo-catalytic activity of the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ hetero-structure in CO$_2$ photo-reduction processes. These results are also supported by experimental findings. The mechanisms of CO$_2$ reduction are discussed in further details in the following section.

3.3. Mechanisms of CO$_2$ Reduction
Upon photo-irradiation of the photo-catalyst, photo-generated electrons (\( \cdot \)) will be transferred to the conduction band of g-C\(_3\)N\(_4\) and Ag\(_2\)PO\(_4\)(111), leaving holes (\( h^+ \)) in the valence band of these semiconductors to catalyze the water oxidation to form the hydrogen source (\( \cdot \)) required for the CO\(_2\) reduction, according to the following reactions:

\[
\begin{align*}
& -3 \rightarrow 4 + h^+ \rightarrow (\cdot) + h^+ \\
& \text{1st} \quad +4 h^+ \rightarrow (\cdot) + 4 h^+
\end{align*}
\]

The overall reactions of CO\(_2\) reduction to form HCOOH, CH\(_2\)O, CH\(_3\)OH and CH\(_4\) using 2, 4, 6 and 8 electrons in the presence of hydrogen are expressed as follows:

\[
\begin{align*}
& 2 + 2 \rightarrow 2 + 2 \\
& 2 + 4 \rightarrow 2 + 2 \\
& 4 + 6 \rightarrow 4 + 2 \\
& 8 + 8 \rightarrow 4 + 2
\end{align*}
\]

The overall reactions above include several elementary hydrogenation steps, which are determined by the most stable product at each step, as shown in Fig. 8; where reaction energies of all elementary steps are listed in Table 1.

The most favorable adsorption geometries of all intermediates are shown in Fig. 9. The initial step of CO\(_2\) hydrogenation is the formation of the formate (HCOO\(^*\)) or the carboxyl species (trans-COOH\(^*\) and/or cis-COOH\(^*\))\(^{62}\). The formate species prefer to adsorb perpendicularly, with two O atoms pointing towards the surface, with short O N distances of 2.879 and 3.012 Å, as shown in Fig. 9. The calculated reaction energy of hydrogenation of CO\(_2\) to HCOO (\( 2^* + ^* \rightarrow ^* \)) is -1.565 eV, i.e. an exothermic reaction, see Table 1. The adsorbed CO\(_2\) could also be...
hydrogenated to a carboxyl group with two cis and trans conformers (Fig. 9) \( 2^+ + ^+ + ^- \rightarrow ^- + ^- ^+ ^+ ^- \), which reactions are also exothermic with energies of -1.983 eV and -1.014 eV for the cis and trans conformer, respectively. As the cis conformer is more stable on the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ hetero-structure, it could possibly be the most abundant intermediate after the first step of CO$_2$ hydrogenation. While cis-COOH adsorbs through its carbon atom at a distance of 1.589 Å from the carbon atom of the g-C$_3$N$_4$ monolayer, trans-COOH points perpendicularly towards the surface through its oxygen atom, as shown in Fig. 9.

Subsequent hydrogenation products of formate and carboxyl species are formic acid (HCOOH$^*$) and dihydroxycarbene (cis-cis, cis-trans and trans-trans HOCOH$^*$). Dihydroxycarbene adsorbs in different configurations due to cis and trans structures on either side of the CO bond, as shown in Fig. 9. The corresponding elementary reactions of this step are \( ^* + ^+ ^+ ^- \rightarrow ^- ^- ^* + ^- ^* + ^* \) and \( ^* + ^- ^* + ^- ^+ \). As shown in Table. 1, the hydrogenation step of formate to formic acid is significantly exothermic on the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ with a reaction energy of -2.275 eV. Formation of formic acid through hydrogenation of the trans carboxyl group is even more exothermic with a reaction energy of -2.826 eV. The calculated reaction energies of hydrogenation of trans and cis carboxyl leading to the production of different conformers of HOCOH$^*$ show that the tt-HOCOH$^*$ conformer is most likely to be formed. As shown in Table. 1, transformation of cc-HOCOH and ct-HOCOH to tt-HOCOH via reactions of \( - ^* \rightarrow - ^* \) and \( - ^* \rightarrow - ^* \) are exothermic by -0.484 eV and -0.026 eV, respectively. As Fig. 9 shows, formic acid points towards the N atom of the g-C$_3$N$_4$ surface through the H atom of its OH group with an H N bond length of 1.865 Å. While the t,t isomer of HOCOH$^*$ bonds to C atom of the surface through its carbon atom with bond length of 1.558 Å, the two other conformers,
c, t and c,c HOCOH*, point toward the surface with their hydrogen atom at distances of 1.657 and 1.846 Å, respectively. As to the produced intermediates, four possible paths leading to CH₃OH and CH₄ formation through either HCOOH* or HOCH* were studied in detail, as shown in Figure 10.

### 3.3.1. The reaction pathways of CO₂ to CH₃OH or CH₄ through HCOOH*

The reaction energy profiles of the different potential pathways are shown in Fig. 10. Produced HCOOH* is less likely to desorb from the surface as this process would be endothermic requiring an energy of 4.532 eV. Subsequent hydrogenation of the produced HCOOH* intermediate can result in the formation of either hydroxymethoxy (H₂COOH*) via * + * with an endothermic reaction (1.898 eV), or a dissociation reaction into formyl (HCO*) and OH* via * + * with an exothermic reaction energy of -1.250 eV. Therefore, formation of H₂COOH* is less likely to happen due to its high reaction energy, but if formed it points to an N atom of the surface via one of its H atoms at a distance of 1.852 Å, (see Fig. 9). The most likely path after the formation of HCOOH* involves its dissociation to HCO*, where the carbon atom of HCO* binds closely to the N atom of the surface with a bond length of 1.409 Å, (Fig. 9).

Further hydrogenation of HCO* can lead to the formation of either formaldehyde (CH₂O*), via * + * + → 2* with an exothermic reaction energy of -0.930 eV, or cis-HCOH* and trans-HCOH*, via * + * + → * and * + * + → * with reaction energies of -0.182 and -0.884 eV, respectively. While the latter species adsorbs perpendicularly on the surface, it prefers to bridge two N atoms of g-C₃N₄ through its C atom with C N bond lengths of 1.465 and 1.524 Å. The carbon atom of cis-HCOH also prefers to bridge C and N atoms of the g-C₃N₄ layer with bond lengths of 1.570 and 1.599 Å. Transformation of c-
HCOH\(^{*}\) to t-HCOH\(^{*}\) is favorable energetically, with an exothermic reaction energy of -0.702 eV. Therefore, further hydrogenation can be continued from t-HCOH\(^{*}\) to CH\(_2\)OH\(^{*}\) by the reaction of \(\text{H}^* + \text{H}^* + \rightarrow 2^*\) releasing an energy of 0.228 eV. The produced CH\(_2\)O\(^{*}\) from HCO\(^{*}\) hydrogenation prefers to lie almost parallel on the surface with the closest distance of 3.492 Å between its carbon atom and the nitrogen of the g-C\(_3\)N\(_4\) monolayer. A large distance between molecule and hybrid structure, in addition to the unchanged geometry after adsorption, shows that formaldehyde adsorbs physically on the hybrid Ag\(_3\)PO\(_4\)/g-C\(_3\)N\(_4\) system (Fig. 9).

Further hydrogenation of CH\(_2\)O\(^{*}\) results in the formation of hydroxymethyl (CH\(_2\)OH\(^{*}\)) or a methoxy species (CH\(_3\)O\(^{*}\)), with exothermic energies of -0.182 and -1.216 eV via reactions of \(\text{H}^* + \text{H}^* + \rightarrow 2^*\) and \(\text{H}^* + \text{H}^* + \rightarrow 3^*\), respectively. As Fig. 9 shows, both the CH\(_2\)OH\(^{*}\) and CH\(_3\)O\(^{*}\) intermediates bond to the carbon of the g-C\(_3\)N\(_4\) monolayer of the hybrid structure, with a C-C distance of 1.580 Å and C-O distance of 1.397 Å, respectively.

CH\(_3\)O\(^{*}\) and CH\(_2\)OH\(^{*}\) can also hydrogenate to form methanol CH\(_3\)OH\(^{*}\) via \(3^* + \text{H}^* + \rightarrow 3^*\) and \(2^* + \text{H}^* + \rightarrow 3^*\) where both reactions are exothermic with reaction energies of -0.419 and -1.453 eV, respectively. The methanol molecule points to the surface by its OH group, where the distance between its H atom and the closest nitrogen atom of the surface is 3.007 Å, (Fig. 9). Thus, methanol production from CO\(_2\) reduction via HCOOH on the Ag\(_3\)PO\(_4\)(111)/g-C\(_3\)N\(_4\) involves a sequence of elementary steps, as shown below:

\(2^* \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow \cdot \rightarrow\)

It should be noted that the largest exothermic reaction energy of -2.826 eV occurs during the hydrogenation of t-COOH\(^{*}\) to HCOOH\(^{*}\) and the smallest reaction energy of -0.182 eV occurs in the hydrogenations of CH\(_2\)O\(^{*}\) to CH\(_2\)OH\(^{*}\) and HCO\(^{*}\) to c-HCOH\(^{*}\).
Dissociation of CH$_2$OH$^*$ to CH$_2^*$ (2 $^*$ $\rightarrow$ 2$^*$ + $^*$) with an exothermic reaction energy of -2.510 eV is another likely reaction, which leads to methane (CH$_4$) production via subsequent hydrogenations of CH$_2^*$ and CH$_3^*$, through 2$^*$ + 2$^*$ + $^*$ $\rightarrow$ 3$^*$ and 3$^*$ + 4$^*$ + $^*$ $\rightarrow$ 4$^*$ reactions, respectively. These reactions are both likely to happen as they are highly exothermic with reaction energies of -1.141 and -1.508 eV. While the carbon of CH$_2^*$ prefers to bond to the nitrogen of g-C$_3$N$_4$ with a bond length of 1.326 Å, CH$_3^*$ adsorbs on top of the carbon atom of g-C$_3$N$_4$ layer with C C bond length of 1.594 Å, and CH$_4^*$ interacts through one of its H atoms at a distance of 2.929 Å from the N atom of g-C$_3$N$_4$. Similarly, the sequence of elementary steps for CH$_4$ production through HCOOH species is as follow:

$$2^* \rightarrow ^*, , \rightarrow ^* \rightarrow ^* \rightarrow ^* \rightarrow 3^* \rightarrow 4^*$$

In this sequence, the largest exothermic reaction energy of -2.826 eV occurs in the hydrogenation of t-COOH$^*$ to HCOOH$^*$ and the smallest reaction energy of -0.182 eV corresponds to CH$_2$OH$^*$ and c-HCOH$^*$ production from CH$_2$O$^*$ and HCO$^*$, respectively.

### 3.3.2. The reaction pathways of CO$_2$ to CH$_3$OH or CH$_4$ through HOCOH

The reaction energy profiles of the pathways are shown in Fig. 10. As discussed before, tt-HOCOH is the most favored conformer of HOCOH whose dissociation leads to formation of COH$^*$ via $^* \rightarrow ^* + ^*$ which is an exothermic reaction by -2.097 eV. COH$^*$ binds through its carbon atom to three nitrogen atoms of g-C$_3$N$_4$ with C N bond lengths of 1.439, 1.460 and 1.487 Å. Further hydrogenation of COH$^*$ to HCOH$^*$ is also exothermic for both cis-HCOH$^*$ and trans-HCOH$^*$ by -1.114 and -1.816 eV, respectively. Similar to the mechanism through HCOOH$^*$ (discussed in section 3.3.1), further hydrogenation of HCOH$^*$ results in production of CH$_2$OH$^*$ and CH$_3$OH$^*$. Produced CH$_2^*$ from the dissociation of CH$_2$OH$^*$ leads to final products of
CH$_3^*$ and CH$_4^*$. In summary, the following paths are involved in the production of CH$_3$OH$^*$ and CH$_4^*$ via HOCOH$^*$, respectively;

While the smallest reaction energy for both paths through HOCHO$^*$ relates to the hydrogenation reaction of t- HCOH$^*$ to CH$_2$OH$^*$ (-0.228 eV), the largest reaction energies for methanol and methane production pathways correspond to the dissociation reactions of tt-HOCHO$^*$ and CH$_2$OH$^*$, with energies of -2.097 and -2.511 eV, respectively.

Desorption of produced CH$_3$OH$^*$, HCOOH$^*$, CH$_2$O$^*$ and CH$_4^*$ needs more energy due to their highly endothermic desorption energies of 4.544, 4.532, 4.235 and 4.213 eV, respectively. Surface coverage of these species; surface hydration; surface reconstruction; and/or increasing the temperature could all reduce the desorption energies to add desorption of the product species. Temperature Programmed Desorption (TPD) could provide further insight into the temperature-dependence of desorption and show the temperatures at which desorption of the relevant species would occur, which could then feed back into mechanistic pathway calculations.

Considering the mechanisms described above and shown in Fig. 10, since CH$_4$ formation is an exothermic reaction releasing as much as 2.43 eV compared to 1.18 eV for the production of CH$_3$OH, CH$_4$ formation is likely to be the most favored pathway on the hybrid Ag$_3$PO$_4$(111)/g-C$_3$N$_4$, via either HCOOH$^*$ or HOCHO$^*$ intermediates, which are both likely to happen thermodynamically. We have also calculated the energetics of a few reactions on the Ag$_3$PO$_4$(111)/Ag/g-C$_3$N$_4$ to see if the presence of the Ag affects the energetics of the reactions and/or the adsorption geometries and energies. However, we did not find any significant changes in the reaction energetics results when the composite includes Ag. A kinetic study determining the
reaction barriers could provide further insight into the reaction pathways of CO$_2$ reduction on the Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ hetero-structure.

4. Conclusions

DFT calculations have been employed to study the hybrid Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ system as a potential (photo-)catalyst in the reduction of CO$_2$. The band gap of the hybrid structure is reduced to 2.52 eV, improving the photocatalytic capability of the Ag$_3$PO$_4$(111) surface and g-C$_3$N$_4$ monolayer under visible light. We have further investigated the mechanism of CO$_2$ reduction to possible hydrocarbons, catalyzed by the hybrid system, where our calculated reaction energies revealed that the production of CH$_4$ is the dominant pathway through either HCOOH$^*$ or HOCOH$^*$ as intermediates. It was found that the largest exothermic reaction energy of -2.826 eV produced during the hydrogenation of t-COOH$^*$ to HCOOH$^*$ and the smallest reaction energy of -0.182 eV for the hydrogenations of CH$_2$O$^*$ to CH$_2$OH$^*$ and HCO$^*$ to c-HCOH$^*$.

Our electronic structure calculations of the ternary Ag$_3$PO$_4$(111)/Ag/g-C$_3$N$_4$ nanocomposite revealed that the Ag atom at the interface of Ag$_3$PO$_4$(111) and g-C$_3$N$_4$ act as a charge recombination center where the charge transfer occurs, promoting the electron-hole separation in the hybrid Ag$_3$PO$_4$(111)/g-C$_3$N$_4$ system through a Z-scheme mechanism, leading to a highly efficient photo-catalyst, as has been seen in experiment. The band structure calculation of the ternary composite confirms the presence of mid-gap states of the atomic Ag at the interface, leading to a smaller band gap and more efficient Z-scheme photo-catalyst.

This study has investigated the fundamental electronic properties of a highly efficient visible light-active photo-catalysts and its activity towards CO$_2$ reduction from a thermodynamic point of view.
A further kinetic study will provide better understanding of the mechanism of CO₂ reduction on the Ag₃PO₄(111)/g-C₃N₄ hybrid structure. Furthermore, doped g-C₃N₄ coupled with Ag₃PO₄(111) has also been suggested experimentally and theoretical studies may help to identify the effects of different dopants on the photo-catalytic activity of the hybrid structure. Finally, other low-index surfaces of Ag₃PO₄ such as {100} could also be investigated as interfaces to be coupled with g-C₃N₄ to see if and how this would affect the photo-catalytic activity of the reaction under similar conditions.
