Dexamethasone in Hospitalized Patients with Covid-19

The RECOVERY Collaborative Group

ABSTRACT

BACKGROUND
Coronavirus disease 2019 (Covid-19) is associated with diffuse lung damage. Glucocorticoids may modulate inflammation-mediated lung injury and thereby reduce progression to respiratory failure and death.

METHODS
In this controlled, open-label trial comparing a range of possible treatments in patients who were hospitalized with Covid-19, we randomly assigned patients to receive oral or intravenous dexamethasone (at a dose of 6 mg once daily) for up to 10 days or to receive usual care alone. The primary outcome was 28-day mortality. Here, we report the final results of this assessment.

RESULTS
A total of 2104 patients were assigned to receive dexamethasone and 4321 to receive usual care. Overall, 482 patients (22.9%) in the dexamethasone group and 1110 patients (25.7%) in the usual care group died within 28 days after randomization (age-adjusted rate ratio, 0.83; 95% confidence interval [CI], 0.75 to 0.93; P<0.001). The proportional and absolute between-group differences in mortality varied considerably according to the level of respiratory support that the patients were receiving at the time of randomization. In the dexamethasone group, the incidence of death was lower than that in the usual care group among patients receiving invasive mechanical ventilation (29.3% vs. 41.4%; rate ratio, 0.64; 95% CI, 0.51 to 0.81) and among those receiving oxygen without invasive mechanical ventilation (23.3% vs. 26.2%; rate ratio, 0.82; 95% CI, 0.72 to 0.94) but not among those who were receiving no respiratory support at randomization (17.8% vs. 14.0%; rate ratio, 1.19; 95% CI, 0.92 to 1.55).

CONCLUSIONS
In patients hospitalized with Covid-19, the use of dexamethasone resulted in lower 28-day mortality among those who were receiving either invasive mechanical ventilation or oxygen alone at randomization but not among those receiving no respiratory support. SEVERE ACUTE RESPIRATORY SYNDROME
coronavirus 2 (SARS-CoV-2), the cause of
coronavirus disease 2019 (Covid-19), emerged
in China in late 2019 from a zoonotic source.\(^1\)
The majority of Covid-19 cases either are asymptom-
tatic or result in only mild disease. However,
in a substantial percentage of patients, a respira-
tory illness requiring hospital care develops,\(^2\)
and such infections can progress to critical illness
with hypoxemic respiratory failure requiring
prolonged ventilatory support.\(^3\) Among pa-
tients with Covid-19 who were admitted to
hospitals in the United Kingdom in the first half
of 2020, the case fatality rate was approximately
26% overall and more than 37% among patients
who were undergoing invasive mechanical venti-
lation.\(^7\) Although remdesivir has been shown to
shorten the time until recovery in hospitalized
patients,\(^8\) no therapeutic agents have been shown
to reduce mortality.

The pathophysiological features of severe
Covid-19 are dominated by an acute pneumonic
process with extensive radiologic opacity and, on
autopsy, diffuse alveolar damage, inflammatory
infiltrates, and microvascular thrombosis.\(^9\) In
other severe viral pneumonias, such as highly
pathogenic avian influenza,\(^10\) SARS,\(^11\) and pan-
demic and seasonal influenza,\(^12\) the host im-
une response is thought to play a key role in
the pathophysiology of organ failure. Inflamma-
tory organ injury may occur in severe Covid-19,
with a subgroup of patients having markedly
elevated levels of inflammatory markers, includ-
ing C-reactive protein, ferritin, interleukin-1, and
interleukin-6.\(^6\) Several therapeutic interven-
tions have been proposed to mitigate inflamma-
tory organ injury in viral pneumonia, but the value
of glucocorticoids has been widely debated.\(^15,16\)

Although one small trial has reported im-
proved clinical outcomes in patients with Covid-19
who were given methylprednisolone,\(^17\) the absence
of reliable evidence from large-scale randomized
clinical trials means there is uncertainty about
the effectiveness of glucocorticoids in patients with
Covid-19. Many guidelines for the treatment of
such patients have stated that glucocorticoids were
either contraindicated or not recommended,\(^18\)
although in China, glucocorticoids have been
recommended for severe cases.\(^19\) However, in the
first 6 months of the pandemic, practice varied
widely across the world: in some series, as many
as 50% of patients were treated with glucocorti-
coids.\(^20,21\) Here, we report the results of the con-
trolled, open-label Randomized Evaluation of
Covid-19 Therapy (RECOVERY) trial of dexameth-
sone in patients hospitalized with Covid-19.
The initial version of the manuscript was drafted by the first and last authors, developed by the writing committee, and approved by all members of the trial steering committee. The funders had no role in the analysis of the data, in the preparation or approval of the manuscript, or in the decision to submit the manuscript for publication. The first and last members of the writing committee vouch for the completeness and accuracy of the data and for the fidelity of the trial to the protocol and statistical analysis plan.

**Randomization**

We collected baseline data using a Web-based case-report form that included demographic data, the level of respiratory support, major coexisting illnesses, suitability of the trial treatment for a particular patient, and treatment availability at the trial site. Randomization was performed with the use of a Web-based system with concealment of the trial-group assignment. Eligible and consenting patients were assigned in a 2:1 ratio to receive either the usual standard of care alone or the usual standard of care plus oral or intravenous dexamethasone (at a dose of 6 mg once daily) for up to 10 days (or until hospital discharge if sooner) or to receive one of the other suitable and available treatments that were being evaluated in the trial.

For some patients, dexamethasone was unavailable at the hospital at the time of enrollment or was considered by the managing physician to be either definitely indicated or definitely contraindicated. These patients were excluded from the randomized comparison between dexamethasone and usual care. The randomly assigned treatment was prescribed by the treating clinician. Patients and local members of the trial staff were aware of the assigned treatments.

**Procedures**

A single online follow-up form was to be completed by the local trial staff when each patient was discharged or had died or at 28 days after randomization, whichever occurred first. Information was recorded regarding the patients’ adherence to the assigned treatment, receipt of other treatments for Covid-19, duration of admission, receipt of respiratory support (with duration and type), receipt of renal dialysis or hemofiltration, and vital status (including the cause of death). In addition, we obtained routine health care and registry data, including information on vital status (with date and cause of death), discharge from the hospital, and respiratory and renal support therapy.

**Outcome Measures**

The primary outcome was all-cause mortality within 28 days after randomization; further analyses were specified at 6 months. Secondary outcomes were the time until discharge from the hospital and, among patients not receiving invasive mechanical ventilation at the time of randomization, subsequent receipt of invasive mechanical ventilation (including extracorporeal membrane oxygenation) or death. Other prespecified clinical outcomes included cause-specific mortality, receipt of renal dialysis or hemofiltration, major cardiac arrhythmia (recorded in a subgroup), and receipt and duration of ventilation. Among those receiving invasive mechanical ventilation at the time of randomization, the outcome of successful cessation of invasive mechanical ventilation was defined as cessation within (and survival to) 28 days. All information presented in this report is based on a data cutoff of December 14, 2020. Information regarding the primary and secondary outcomes is complete for 99.9% of trial participants.

**Statistical Analysis**

As stated in the protocol, appropriate sample sizes could not be estimated when the trial was being planned at the start of the Covid-19 pandemic. As the trial progressed, the trial steering committee, whose members were unaware of the results of the trial comparisons, determined that if 28-day mortality was 20%, then the enrollment of at least 2000 patients in the dexamethasone group and 4000 in the usual care group would provide a power of at least 90% at a two-sided P value of 0.01 to detect a clinically relevant proportional reduction of 20% (an absolute difference of 4 percentage points) between the two groups. Consequently, on June 8, 2020, the steering committee closed recruitment to the dexamethasone group, since enrollment had exceeded 2000 patients.

For the primary outcome of 28-day mortality, the hazard ratio from Cox regression was used...
to estimate the mortality rate ratio. Kaplan–Meier survival curves were constructed to show cumulative mortality over the 28-day period. Cox regression was also used to analyze the secondary outcome of hospital discharge within 28 days and the outcome of successful cessation of invasive mechanical ventilation. For both of these outcomes, data for patients who had died during hospitalization were censored on day 29. For the prespecified composite secondary outcome of invasive mechanical ventilation or death within 28 days (among patients who were not receiving invasive mechanical ventilation at randomization), the precise date of invasive mechanical ventilation was not available, so a log-binomial regression model was used to estimate the risk ratio. Risk ratios were also estimated for the outcomes of receipt of noninvasive or invasive mechanical ventilation (among patients who were not receiving oxygen or invasive mechanical ventilation at the time of randomization) and receipt of renal-replacement therapy (among those not receiving such therapy at the time of randomization).

Through the play of chance in the unstratified randomization, the mean age was 1.1 years older among patients in the dexamethasone group than among those in the usual care group (Table 1). To account for this imbalance in an important prognostic factor, estimates of rate and risk ratios were adjusted for the baseline age in three categories (<70 years, 70 to 79 years, and ≥80 years). This adjustment was not specified in the first version of the statistical analysis plan but was added once the imbalance in age became apparent. Results without age adjustment (corresponding to the first version of the analysis plan) are provided in the Supplementary Appendix.

Prespecified analyses of the primary outcome were performed in six subgroups, as defined by characteristics at randomization: age, sex, race, level of respiratory support, days since symptom onset, and predicted 28-day mortality risk. In prespecified subgroups, we estimated rate ratios (or risk ratios in some analyses) and their confidence intervals using regression models that included an interaction term between the treatment assignment and the subgroup of interest. Chi-square tests for heterogeneity or linear trend across the subgroup-specific log estimates were then performed in accordance with the prespecified plan.

All P values are two-sided and are shown without adjustment for multiple testing. All analyses were performed according to the intention-to-treat principle. The full database is held by the trial team, which collected the data from trial sites and performed the analyses at the Nuffield Department of Population Health, University of Oxford.

**RESULTS**

**PATIENTS**

Of the 11,303 patients who underwent randomization from March 19 to June 8, 2020, a total of 9355 (83%) were eligible to receive dexamethasone (i.e., the drug was available in the hospital at the time and the patient had no known indication for or contraindication to dexamethasone). Of these patients, 6425 underwent randomization to receive either dexamethasone (2104 patients) or usual care alone (4321 patients) (Fig. 1). The remaining patients were randomly assigned to one of the other treatment groups being evaluated in the trial.

The mean (±SD) age of the patients in this comparison was 66.1±15.7 years, 36% of the patients were female, and 18% were Black, Asian, or from a minority ethnic group (Table 1 and Table S1 in the Supplementary Appendix). A history of diabetes was present in 24% of the patients, heart disease in 27%, and chronic lung disease in 21%, with 56% having at least one major coexisting illness recorded. In this analysis, 89% of the patients had laboratory-confirmed SARS-CoV-2 infection. At randomization, 16% were receiving invasive mechanical ventilation or extracorporeal membrane oxygenation, 60% were receiving oxygen only (with or without noninvasive ventilation), and 24% were receiving neither.

In the dexamethasone group, 95% of the patients received at least one dose of a glucocorticoid (Table S2). The median duration of treatment was 7 days (interquartile range, 3 to 10). In the usual care group, 8% of the patients received a glucocorticoid as part of their clinical care. The use of azithromycin or another macrolide antibiotic during the follow-up period was similar in the dexamethasone group and the usual care group (24% vs. 26%), and 0 to 3% of patients...

* Plus–minus values are means ±SD. HIV denotes human immunodeficiency virus, IQR interquartile range, NA not applicable, and SARS-CoV-2 severe acute respiratory syndrome coronavirus 2.
† There was a significant (P=0.01) difference in the mean age between patients in the dexamethasone group and those in the usual care group, but there were no significant differences between the groups in any other baseline characteristic.
‡ Among the women, 1 in the dexamethasone group and 3 in the usual care group were pregnant.
§ Race or ethnic group was recorded in the patient’s electronic health record.
¶ Data regarding the number of days since symptom onset were missing for 4 patients in the dexamethasone group and 13 patients in the usual care group; these patients were excluded from estimates of the median number of days since onset.
‖ Severe liver disease was defined as requiring ongoing specialist care.
** Severe kidney impairment was defined as an estimated glomerular filtration rate of less than 30 ml per minute per 1.73 m².
received hydroxychloroquine, lopinavir–ritonavir, or interleukin-6 antagonists during follow-up (Table S2). After remdesivir became available in the United Kingdom on May 26, 2020, the drug was administered to 3 patients before randomization and 2 patients during the follow-up period (Table S2).

**Primary Outcome**
Mortality at 28 days was significantly lower in the dexamethasone group than in the usual care group, with deaths reported in 482 of 2104 patients (22.9%) and in 1110 of 4321 patients (25.7%), respectively (rate ratio, 0.83; 95% confidence interval [CI], 0.75 to 0.93; \( P < 0.001 \))
Dexamethasone in Hospitalized Patients with Covid-19

(Fig. 2A). In a prespecified analysis according to the level of respiratory support that the patients were receiving at randomization, there was a trend showing the greatest absolute and proportional benefit among patients who were receiving invasive mechanical ventilation (11.6 by chi-square test for trend) (Fig. 3). In the dexamethasone group, the incidence of death was lower than that in the usual care group among patients receiving invasive mechanical ventilation (29.3% vs. 41.4%; rate ratio, 0.64; 95% CI, 0.51 to 0.81) and in those receiving oxygen with-
out invasive mechanical ventilation (23.3% vs. 26.2%; rate ratio, 0.82; 95% CI, 0.72 to 0.94) (Fig. 2B and 2C). However, there was no clear effect of dexamethasone among patients who were not receiving any respiratory support at randomization (17.8% vs. 14.0%; rate ratio, 1.19; 95% CI, 0.92 to 1.55) (Fig. 2D). The results were similar in a post hoc exploratory analysis restricted to the 5744 patients (89.4%) with a positive SARS-CoV-2 test result. Likewise, sensitivity analyses without adjustment for age resulted in similar findings (Table S3).

Patients who were receiving invasive mechanical ventilation at randomization were on average 10 years younger than those not receiving any respiratory support and had a history of symptoms before randomization for an average of 7 days longer (Table 1 and Table S4). The age-adjusted absolute reductions in 28-day mortality associated with the use of dexamethasone were 12.3 percentage points (95% CI, 6.2 to 17.6) among the patients who were receiving invasive mechanical ventilation and 4.2 percentage points (95% CI, 1.4 to 6.7) among those receiving oxygen only.

Patients with a longer duration of symptoms (who were more likely to have been receiving invasive mechanical ventilation at randomization) had a greater mortality benefit in response to treatment with dexamethasone. The receipt of dexamethasone was associated with a reduction in 28-day mortality among those with symptoms for more than 7 days but not among those with a more recent symptom onset (12.4 by chi-square test for trend) (Fig. S1).

SECONDARY OUTCOMES

Patients in the dexamethasone group had a shorter duration of hospitalization than those in the usual care group (median, 12 days vs. 13 days) and a greater probability of discharge alive within 28 days (rate ratio, 1.10; 95% CI, 1.03 to 1.17) (Table 2). The greatest effect regarding discharge within 28 days was seen among patients who were receiving invasive mechanical ventilation at randomization (11.7 by chi-square test for trend) (Fig. S2A and Fig. S3).

Among the patients who were not receiving invasive mechanical ventilation at randomization, the number of patients who progressed to the prespecified composite secondary outcome of invasive mechanical ventilation or death was lower in the dexamethasone group than in the usual care group (risk ratio, 0.93; 95% CI, 0.85 to 1.01) (Table 2). This effect was greater among the patients who were receiving oxygen at randomization (6.3 by chi-square test for trend) (Fig. S2B). Other prespecified analyses of the effects of dexamethasone on these secondary outcomes among different categories of patients are shown in Figures S4 and S5.

OTHER PRESPECIFIED CLINICAL OUTCOMES

Among patients who were not receiving invasive mechanical ventilation at randomization, the risk of progression to invasive mechanical ventilation...
was lower in the dexamethasone group than in the usual care group (risk ratio, 0.79; 95% CI, 0.64 to 0.97) (Table 2). Among those who were receiving invasive mechanical ventilation at randomization, successful cessation of invasive mechanical ventilation was more likely in the dexamethasone group than in the usual care group (rate ratio, 1.47; 95% CI, 1.20 to 1.78) (Table 2 and Fig. S6). Among the patients who were not receiving renal-replacement therapy (renal dialysis or hemofiltration) at randomization, the number of patients who received this treatment within 28 days was lower in the dexamethasone group than in the usual care group (risk ratio, 0.61; 95% CI, 0.48 to 0.76) (Table 2).

Most deaths were due to Covid-19, and such deaths were less frequent in the dexamethasone group than in the usual care group (Table S5). The incidence of death from other causes was similar in the dexamethasone group and the usual care group. In the subgroup of patients with available data, the incidence of new cardiac arrhythmia was similar in the dexamethasone group and the usual care group (Table S6). There were four reports of a serious adverse reaction that was deemed by the investigators to be related to dexamethasone: two of hyperglycemia, one of gastrointestinal hemorrhage, and one of psychosis (all recognized adverse effects of glucocorticoids).

### DISCUSSION

Our results show that among hospitalized patients with Covid-19, the use of dexamethasone for up to 10 days resulted in lower 28-day mortality than usual care in patients who were receiving invasive mechanical ventilation at randomization (by 12.3 age-adjusted percentage points, a proportional reduction of approximately one third) and those who were receiving oxygen without invasive mechanical ventilation (by 4.2 age-adjusted percentage points, a proportional reduction of approximately one fifth). However,
there was no evidence that dexamethasone provided any benefit among patients who were not receiving respiratory support at randomization, and the results were consistent with possible harm in this subgroup. The benefit was also clear in patients who were being treated more than 7 days after symptom onset, when inflammatory lung damage is likely to have been more common. A subsequent meta-analysis of seven trials of glucocorticoids for critically ill patients with Covid-19, including RECOVERY, has confirmed the findings of our trial.22 Our results also show that among the patients who were receiving oxygen, the use of dexamethasone was associated with a lower risk of invasive mechanical ventilation or, for those already receiving invasive mechanical ventilation, a greater chance of successful cessation. In both these groups, the use of dexamethasone increased the chance of being discharged from the hospital alive within 28 days.

The RECOVERY trial was designed to provide a rapid and robust assessment of the effect of readily available potential treatments for Covid-19 on 28-day mortality. Approximately 10% of all hospitalized patients with Covid-19 in the United Kingdom were enrolled in the trial, and mortality in the usual care group was consistent with the overall case fatality rate for hospitalized patients with Covid-19 in the United Kingdom at the time that the dexamethasone comparison was active.7 Only essential data were collected at hospital sites, with additional information (including longer-term mortality) ascertained through linkage with routine data sources.

We did not collect information on physiologic, laboratory, or virologic measures. The protocol combines the methods that were used in large, simple trials of treatments for acute myocardial infarction in the 1980s with the opportunities provided by digital health care in the 2020s.23-25 The trial has progressed rapidly, as is essential for studies during epidemics.26 The preliminary results for dexamethasone were announced on June 16, 2020, less than 100 days after the protocol was first drafted, and were adopted into U.K. practice later the same day.27

Glucocorticoids have been widely used in syndromes closely related to Covid-19, including SARS, Middle East respiratory syndrome (MERS), severe influenza, and community-acquired pneumonia. However, the evidence to support or discourage the use of glucocorticoids under these conditions has been weak owing to the lack of data from sufficiently powered randomized, controlled trials.28-31 In addition, the evidence base has suffered from heterogeneity in glucocorticoid doses, medical conditions, and disease severity. It is likely that the beneficial effect of glucocorticoids in severe viral respiratory infections is dependent on the selection of the right dose, at the right time, in the right patient. High doses may be more harmful than helpful, as may such treatment given at a time when control of viral replication is paramount and inflammation is minimal. Slower clearance of viral RNA has been observed in patients with SARS, MERS, and influenza who were treated with systemic glucocorticoids, but the clinical significance of these findings is unknown.29,32,33 Unlike with SARS, in which viral replication peaks in the second week of illness,34 viral shedding in SARS-CoV-2 appears to be higher early in the illness and declines thereafter.35-38 The greater mortality benefit of dexamethasone in patients with Covid-19 who are receiving respiratory support and among those recruited after the first week of their illness suggests that at that stage the disease may be dominated by immunopathological elements, with active viral replication playing a secondary role. This hypothesis would caution against extrapolation of the effect of dexamethasone in patients with Covid-19 to patients with other viral respiratory diseases with a different natural history.

The RECOVERY trial provides evidence that treatment with dexamethasone at a dose of 6 mg once daily for up to 10 days reduces 28-day mortality in patients with Covid-19 who are receiving respiratory support. We found no benefit (and the possibility of harm) among patients who did not require oxygen. Before the completion of the trial, many Covid-19 treatment guidelines stated that the use of glucocorticoids was either contraindicated or not recommended.18 Dexamethasone is on the list of essential medicines of the World Health Organization and is readily available worldwide at low cost. Guidelines issued by the U.K. chief medical officers, the European Medicines Agency, the World Health Organization, and the National Institutes of Health in the United States have been updated to recommend
the use of glucocorticoids in patients hospitalized with Covid-19 requiring oxygen with or without ventilatory support.27,29,40
