A 18-year-old woman is brought to the emergency department after having had a seizure. She was up late with friends the night before and drank some alcohol. Shortly after waking this morning, she collapsed without warning, injuring her face. Her boyfriend witnessed her having a generalized tonic–clonic seizure with cyanosis during which she bit the side of her tongue. Her first memory was waking in the ambulance. She has had no previous seizures; specifically, she has not had any involuntary jerks of the arms and legs on awakening, blank spells, or sensitivity to flashing lights (e.g., sunlight flashing through trees, as seen while riding in a car). How should this patient be further evaluated and treated?
history taking can usually distinguish the three main causes of transient loss of consciousness: epileptic seizure (provoked or unprovoked), syncope (reflex, orthostatic, or cardiac), and psychogenic nonepileptic seizure (which mimics a seizure but is caused by psychological distress rather than abnormal electrical activity in the brain).

Provoked seizures might follow transient cerebral insults such as alcohol withdrawal, the use of illicit drugs such as cocaine and methamphetamine, and metabolic disturbances (e.g., hypoglycemia or hyponatremia). They also may suggest a structural cause such as hemorrhagic stroke, encephalitis, venous sinus thrombosis, or tumor.

Seizures and epilepsy are classified according to seizure type (generalized, focal, or unknown), epilepsy type, and epilepsy syndrome. Table 3 and Table S1 provide common examples of each.

The presentation of a seizure depends on its site of onset (generalized or focal) and pattern of spread. Seizures can occur at any age and in any situation. In some cases, a lack of warning suggests a generalized onset, although a lack of warning is also compatible with focal-onset seizures, especially in the frontal lobe. In other cases (usually focal-onset seizures), there is a specific but often “indescribable” aura — such as déjà vu, an epigastric “rising” sensation, or tastes or smells — usually followed by transient altered awareness.

A convulsive seizure typically has a tonic (stiffening) phase and then a clonic (convulsing) phase. Together these phases last 1 to 3 minutes, typically while the patient has open eyes, apnea, and cyanosis. Patients awaken many minutes later feeling tired and achy, and they sometimes have a lateral tongue bite.

Physical examination may reveal findings that point to a cause other than seizure or a condition predisposing to seizure. Attention should be paid to the skin (e.g., to detect facial angiofibromas, hypomelanotic macules suggestive of tuberous sclerosis, or scars from self-harm that are often associated with psychogenic nonepileptic seizures), the cardiovascular system (an aortic ejection murmur may indicate cardiac syncope, and postural blood-pressure changes may indicate orthostatic hypotension), and findings on funduscopic examination (e.g., elevated intracranial pressure).

Basic blood tests to measure levels of electrolytes, glucose, calcium, and magnesium may help to identify potential causes of seizure or coexisting conditions. An evaluation with 12-lead electrocardiography (ECG) is indicated in all patients (especially older adults) who have had a first seizure or unexplained blackout spell to look for evidence of previous myocardial infarction because of the risk of ventricular tachycardia or of rare but potentially fatal (and often familial) disorders, including hypertrophic cardiomyopathy and long QT syndromes.

**BRAIN IMAGING**

Urgent brain imaging is warranted in patients who present with a first epileptic seizure. Com-
Computed tomography is useful and widely available. However, in most adults with a first seizure (especially a focal-onset seizure) or early epilepsy, detailed magnetic resonance imaging (MRI; ideally 3-T MRI with <3-mm slice thickness on T2-weighted imaging and fluid-attenuated inversion recovery) is warranted to identify more subtle underlying causes such as hippocampal sclerosis, focal cortical dysplasia, or tumor that may be treated surgically.

**Electroencephalography**

Interictal EEG that is performed in a patient who has had a first seizure is unlikely to capture another seizure, although the procedure may provoke psychogenic nonepileptic seizures. EEG is most informative in patients younger than 25 years of age because these patients are most likely to have subclinical interictal generalized activity that may confirm a generalized seizure tendency and that strongly predicts further seizures (70% positive predictive value).\(^{12,13}\)

EEG that is performed soon after a patient has had a first seizure identifies more epileptiform abnormalities than later EEG; one study involving 300 consecutive adults and children identified abnormalities in 51% of those who underwent EEG within 24 hours and in 34% of those who underwent EEG later.\(^{14}\) EEG that is performed in ambulatory or sleep-deprived patients further increases the diagnostic yield in patients in whom an epileptic seizure is likely even though the routine interictal EEG findings are normal.\(^{15}\) The presence of interictal epileptiform discharges in either of these investigations increases the 1-year risk of seizure recurrence by a factor of 1.5.\(^{16}\)

### Management

**Antiseizure Medications**

The medical management of epilepsy predominantly involves seizure suppression with the long-term use of oral medication (Table 4 and Table S2). Antiseizure medication is primarily indicated when the risk of further spontaneous seizures is judged to exceed 60% over the next 10 years.

The aim of management is no seizures and minimal adverse effects of treatment. However, if these goals prove to be impossible, then the priority is complete control of major convulsive seizures, which are potentially dangerous because they may increase the risk of sudden unexpected death in epilepsy (SUDEP) above the estimated absolute risk among patients with epilepsy overall (1.2 cases per 1000 patient-years).\(^{23}\)

The initiation of long-term use of antiseizure medication is a major decision that is made by the patient and the clinician. This decision requires reasonable certainty of an epilepsy diagnosis; the use of medication for a trial period in patients in whom the diagnosis is uncertain should be avoided.

The Medical Research Council Multicentre Trial for Early Epilepsy and Single Seizures\(^{24}\) showed that the risk of seizure recurrence was

† Data are from Derry.7
lower in the first 2 years after the first seizure among patients who received immediate initiation of medication (generally carbamazepine or sodium valproate) than among those who received delayed treatment pending a second seizure (32% vs. 39%), but earlier initiation of treatment did not affect longer-term seizure remission. Adverse events were significantly more common with immediate treatment than with delayed treatment (in 39% and 31% of the patients), and quality-of-life measures were similar in the two groups. Therefore, clinicians usually advise withholding medication in patients who have had a single seizure unless the recurrence risk is particularly high. Despite a low estimated risk of recurrence, some patients choose to receive medication because they have had a particularly severe or injurious first seizure or because they live in areas such as the United Kingdom where a second seizure might extend the driving restriction from 6 months to 12 months.

**Factors Guiding Medication Choice**

The choice of medication should be guided by the type of seizure and epilepsy syndrome (broadly, valproate or levetiracetam is used in patients with generalized-onset seizures and lamotrigine or levetiracetam is used in those with focal-onset seizures) as well as by the effectiveness, adverse-event profile, and pharmacodynamic and pharmacokinetic properties of a given drug. Coexisting conditions must also be considered. For example,

<th>Dose in Adults</th>
<th>Adverse Effects</th>
<th>Interactions</th>
<th>Comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Lamotrigine (Lamictal) for focal-onset seizures(^{17,18}); effective for generalized-onset tonic–clonic seizures but may exacerbate myoclonus and absences</td>
<td>Stabilizes voltage-dependent sodium channels; 50% protein-bound; metabolized in liver; half-life of 12–60 hr</td>
<td>Monotherapy: start 25 mg daily (introduce slowly to avoid rash); initial maintenance therapy, 100–200 mg daily, in 1 or 2 doses</td>
<td>Dose-related effects: drowsiness, insomnia, headache, diplopia; idiosyncratic effect: rash (in approximately 3.5% of patients(^{19}) sometimes severe in children (Stevens–Johnson syndrome), especially when taken with valproate; teratogenicity: dose-related low risk of major malformations and oral clefts</td>
<td>Effect on other agents: increases carbamazepine epoxide (dizziness, diplopia); with higher doses (&gt;300 mg daily), lowers contraceptive pill concentration (uncertain mechanism) but no definite evidence of contraception failure; effect of other agents: valproate inhibits its metabolism, so that only half the usual dose of valproate is necessary; hormonal contraceptives and pregnancy lower its concentration, potentially with breakthrough seizures</td>
<td>Slowly introduced to avoid rash, so therapeutic dose not reached for 4–6 wk, and additional antiseizure medication may be warranted in that time; important interactions with other antiseizure medications (notably valproate or carbamazepine) warrant dose adjustments; data support safety in pregnancy (early concern regarding increased risk of cleft defect not supported by subsequent studies); serum concentration decreases in pregnancy, so consider measuring serum concentration and temporary dose increases to avoid breakthrough seizures</td>
</tr>
<tr>
<td>Levetiracetam (Keppra, Roweepra, and Spritam) for focal-onset seizures(^{18,20}) or generalized-onset seizures(^{21}); first-line treatment for focal-onset seizures in selected patients and for generalized-onset seizures in women of childbearing potential</td>
<td>Binds to synaptic vesicle glycoprotein 2A; not protein-bound; not metabolized in liver; excreted by kidneys largely unchanged; half-life of 6–8 hr</td>
<td>Start 250 mg daily; initial maintenance therapy, 1000–2000 mg daily divided into 2 doses</td>
<td>Dose-related effect: fatigue; idiosyncratic effects: irritability, anxiety, and mood changes; teratogenicity: low risk of major malformations</td>
<td>Effect on other agents: no major effects, but monitor for toxic effects (e.g., double vision and dizziness) if added to carbamazepine; effect of other agents: no major effects</td>
<td>Effective for both focal-onset and generalized-onset seizures; therapeutic dose achieved quickly, so widely used for rapid seizure control; no medication interactions, so suitable for patients receiving other medications (e.g., warfarin); data support good safety profile in pregnancy</td>
</tr>
</tbody>
</table>
patients with substantial anxiety may prefer lamotrigine over levetiracetam, whereas those with obesity or migraines may choose topiramate, which can suppress appetite and reduce the incidence of headaches. An overriding consideration for women is the effects of medication on potential pregnancy.

Although a detailed discussion of the use of antiseizure medication in women who may become pregnant is beyond the scope of this article, so-called “at risk” medications, including sodium valproate, should be avoided in women of childbearing potential; if valproate is used, effective measures should be taken to prevent pregnancy unless the woman is fully informed about the risks. As part of a licensing agreement since 2018 in the United Kingdom and the European Union, women who receive valproate must use highly reliable contraception (a hormonal implant or an intrauterine device) or undergo monthly pregnancy tests, and they must sign an annual risk-acknowledgment form.

The possible contribution of maternal seizures to the risks of congenital anomalies and neurodevelopmental delay remains unclear. The EURAP study also showed that valproate carries high risks in pregnancy. Approximately 10% of babies exposed to sodium valproate in utero have major congenital anomalies, and up to 40% have measurable neurodevelopmental delay. In the European Registry of Antiepileptic Drugs and Pregnancy (EURAP) Group prospective study involving 7555 pregnancies, *10.3% of the infants had major congenital malformations after in utero exposure to valproate, 5.5% had these malformations after exposure to carbamazepine, 3.9% after topiramate, 3.0% after oxcarbazepine, 2.9% after lamotrigine, and 2.8% after levetiracetam (as compared with a 2.6% risk among infants who had not been exposed to in utero antiseizure medication).

The possible contribution of congenital anomalies to the risks of neurodevelopmental delay includes cardiac defects and hypospadias, each of which was found in 2% of infants with exposure to valproate; cleft lip, gastrointestinal, renal, and neural-tube defects; and polydactyly. Cognitive assessments in 6-year-old children who had in utero exposure to valproate showed significant dose-related inverse associations with IQ, verbal ability, and nonverbal ability; these effects were not observed in children with in utero exposure to other antiseizure medications. This valproate should generally be avoided in women of childbearing potential; if valproate is used, effective measures should be taken to prevent pregnancy unless the woman is fully informed about the risks. As part of a licensing agreement since 2018 in the United Kingdom and the European Union, women who receive valproate must use highly reliable contraception (a hormonal implant or an intrauterine device) or undergo monthly pregnancy tests, and they must sign an annual risk-acknowledgment form.
Data from pregnancy registries have shown no consistent safety signals for lamotrigine or levetiracetam and no clear evidence of neurodevelopmental delay associated with these agents. In observational studies, maternal folate supplementation has been associated with a reduced risk of neurocognitive abnormalities among babies with in utero exposure to antiseizure medications, and such supplements are routinely recommended in women who may become pregnant while receiving such medication.

**Effectiveness of Medications**

A single-center observational study involving 525 patients with epilepsy of various types showed that approximately half became seizure-free for at least 1 year after they began to receive a first antiseizure medication. Many randomized, controlled trials of the efficacy of new antiseizure medications have assessed their use as add-on medications in patients with treatment-resistant epilepsy. In these short-term trials, these new medications reduced the frequency of seizures 2 to 4 times more than placebo but often at doses that were higher than those generally used in practice.

The management of epilepsy, which is a long-term condition, is largely informed by the Standard and New Antiepileptic Drugs (SANAD) trials, which involved long-term, head-to-head, unblinded comparisons of existing standard agents with newer medications. The first SANAD trial involving patients with generalized and unclassified epilepsies compared valproate (then the standard of care) with lamotrigine or topiramate and showed the superiority of valproate over topiramate with respect to treatment failure and the superiority over lamotrigine with respect to 12-month remission. For focal epilepsies, lamotrigine was superior to carbamazepine (then the standard of care), gabapentin, and topiramate with respect to treatment failure and was noninferior to carbamazepine with respect to 12-month remission. More recently, the SANAD II trial involving patients with generalized and unclassified epilepsies did not show noninferiority of levetiracetam to valproate with respect to 12-month remission; valproate resulted in a higher incidence of 12-month remission (36% vs. 26%) and a similar incidence of adverse events, and it was more cost-effective. For focal epilepsies, zonisamide but not levetiracetam was noninferior to lamotrigine with respect to 12-month remission; however, as compared with both levetiracetam and zonisamide, lamotrigine resulted in lower incidences of treatment failure and adverse events, and it was more cost-effective.

Thus, the first-line medication for patients with generalized-onset seizures is sodium valproate, or levetiracetam for girls and women of childbearing potential. For patients with focal-onset seizures, lamotrigine is usually the first-line medication, although levetiracetam or other agents may have advantages in some patients (Table 4 and Fig. S2).

The main disadvantage of lamotrigine is its slow starting dose, with increases to the full treatment dose over a period of several weeks. This gradual dose adjustment is necessary to reduce the risk of the Stevens–Johnson syndrome and toxic epidermal necrolysis (from 1.0% to approximately 0.01 to 0.10%); initial coverage with another antiseizure medication may be warranted. The main adverse effects of levetiracetam are irritability and anxiety, especially in patients with preexisting anxiety.

**Lifestyle Factors**

Clinicians should engage in joint decision making with patients and share verbal and written information. Information on driving eligibility is particularly important. In the United Kingdom and the European Union, a 6-month driving restriction is mandated for patients who have had a single seizure with a low risk of recurrence, and a 12-month restriction is mandated for patients with epilepsy, including those who have had a single seizure and who have a high risk of recurrence (e.g., those with an abnormal EEG, neurologic deficit, or both). In the United States, eligibility for a driver's license in persons who have had a single seizure or in those with epilepsy varies among states, although the rules are generally less restrictive than those in Europe.

Advice from clinicians regarding other activities depends on the characteristics and frequency of the patient's seizures; these factors are balanced against individual priorities. Clinicians should inform patients of the risks associated with seizures, including drowning and SUDEP; the likelihood of seizure recurrence (Table 1); and suggested lifestyle modifications (e.g., avoiding being alone during certain activities such as caring for children or bathing, so that another...
person can help if a seizure occurs, and appreciating the risks of ladders and heights).

Patients should be encouraged to adhere to the regimen of antiseizure medication and a regular sleep schedule and to limit the use of alcohol. Considerable observational data provide support for a relationship between insufficient sleep and seizure risk or abnormal EEG activity. A short-term randomized trial involving 84 patients with medication-resistant focal epilepsy in whom the dose of antiseizure medication was being tapered showed no significant differences in seizure frequency between the group of patients with sleep deprivation and the control group. However, these trial findings may not be applicable to patients with early epilepsy, and the promotion of sleep hygiene in patients with epilepsy remains prudent. Alcohol use is an important seizure precipitant, mainly because of the risk of seizure during alcohol withdrawal and the tendency of alcohol to disrupt sleep, interfere with adherence to antiseizure medications, or both. A meta-analysis of observational studies showed a dose–response relationship between the amount of alcohol consumed daily and the probability of development of epilepsy; for an average of 4, 6, and 8 drinks daily, the relative risks were 1.81 (95% confidence interval [CI], 1.59 to 2.07), 2.44 (95% CI, 2.00 to 2.97), and 3.27 (95% CI, 2.52 to 4.26). Alcohol abstinence is probably unnecessary, but consumption should be limited to modest amounts. Illicit drugs that disrupt sleep, especially cocaine and amphetamine, should be avoided, but high-quality data on the recreational use of cannabis in persons with epilepsy are lacking.

**Areas of Uncertainty**

The clinical diagnosis of epilepsy may be incorrect in up to 20% of patients unless episodes are captured on EEG with video. Many patients with a diagnosis of epilepsy are later recognized to have psychogenic seizures, and additional psychogenic seizures may later develop in persons with established epilepsy. Clinicians must repeatedly question the diagnosis in patients with medication-resistant epilepsy.

The potential long-term effects of new antiseizure medications, which are typically prescribed as lifelong treatments, warrant further study. Notoriously, for 8 years after licensing, vigabatrin was used worldwide to manage seizures until it was recognized that long-term use of this agent caused permanent visual-field defects in more than half of patients. Data are lacking to inform pregnancy and offspring outcomes associated with new antiseizure medications; several worldwide pregnancy registries regularly update clinicians on the teratogenicity of these agents (Table S3).

**Genetic characterization** has enabled both targeting of more effective treatments for some complex epilepsies (e.g., stiripentol for the Dravet syndrome and a ketogenic diet for glucose transporter type 1 deficiency syndrome) and screening for the HLA-B*1502 allele in Han Chinese populations to predict the carbamazepine-induced Stevens–Johnson syndrome. Further understanding of the effect of genetic factors on the risk of recurrent seizures and on the efficacy and risks of various medications is needed to guide treatment decisions.

**Guidelines**

In 2015, the American Academy of Neurology and the American Epilepsy Society provided joint guidelines on the management of unprovoked first seizure in adults. The 2012 guidelines of the National Institute for Health and Care Excellence in the United Kingdom are undergoing revision. The current recommendations differ from these older guidelines with respect to specific medications recommended, since the results of the SANAD II trial were published after these guidelines were issued.

**Conclusions and Recommendations**

In the patient described in the vignette, the first generalized tonic–clonic seizure developed after sleep loss and alcohol use. Careful questioning revealed that this was an isolated event, with no previous myoclonic jerks or absences. Evaluation should include MRI of the head, interictal EEG, and 12-lead ECG. I would discuss with the patient lifestyle factors such as the importance of regular sleep and limiting alcohol consumption, the risks associated with seizures (including drowning and SUDEP), and driving eligibility. Antiseizure medications are not routinely recommended for patients who have had a single seizure;
however, if interictal EEG showed spike-and-wave activity, indicating a high risk of recurrent seizure, I would recommend initiation of an antiseizure medication. Provided that this patient did not have depression or anxiety, I would favor levetiracetam administered with a folate supplement since the patient is of childbearing potential. I would arrange follow-up in 2 months to review the patient’s response and adherence to the medication regimen and any adverse effects.
