ABSTRACT

Observing nearby galaxies with submillimeter telescopes on the ground has two major challenges. First, the brightness is significantly reduced at long submillimeter wavelengths compared to the brightness at the peak of the dust emission. Second, it is necessary to use a high-pass spatial filter to remove atmospheric noise on large angular scales, which has the unwelcome side effect of also removing the galaxy’s large-scale structure. We have developed a technique for producing high-resolution submillimeter images of galaxies of large angular size by using the telescope on the ground to determine the small-scale structure (the large Fourier components) and a space telescope (Herschel or Planck) to determine the large-scale structure (the small Fourier components). Using this technique, we are carrying out the HARP and SCUBA-2 High Resolution Terahertz Andromeda Galaxy Survey (HASHTAG), an international Large Program on the James Clerk Maxwell Telescope, with one aim being to produce the first high-fidelity high-resolution submillimeter images of Andromeda. In this paper, we describe the survey, the method we have developed for combining the space-based and ground-based data, and we present the first HASHTAG images of Andromeda at 450 and 850 µm. We also have created a method to predict the CO(J=3–2) line flux across M 31, which contaminates the 850 µm band. We find that while normally the contamination is below our sensitivity limit, it can be significant (up to 28%) in a few of the brightest regions of the 10 kpc ring. We therefore also provide images with the predicted line emission removed.

Keywords: galaxies: individual (M31) - galaxies: ISM - galaxies: star formation - submillimeter: galaxies - methods: observations - submillimeter: ISM

1. INTRODUCTION

The Andromeda galaxy (Messier 31) is possibly the most frequently observed galaxy in the sky. Galaxies in the Local Group are important for the obvious reason that they are closest, allowing us to study galaxies in the greatest possible detail, but they are also important because they are the only galaxies in which we can detect large numbers of individual stars. The ability to see stars adds a large number of investigative tools to the astronomer’s toolkit, which are not possible to use on galaxies outside the Local Group.

There are only three spiral galaxies in the Local Group: our own, Andromeda, and the Triangulum (Messier 33). The Triangulum has a mass roughly ten times less than our own, but Andromeda has a mass and other properties that are quite similar to our own (Yin et al. 2009). However, there are also some interesting differences. Andromeda has a larger bulge (Yin et al. 2009), less obvious spiral arms (Gordon et al. 2006; Kirk et al. 2015), and much of the star formation in the galaxy is occurring in a large ring (Ford et al. 2013). The cause of this ring is unknown. One interesting suggestion is that the ring may be the result of the dwarf galaxy M 32 passing through the center of the disk, generating a density wave, and thus a wave of star birth that propagates outward through the disk (Block et al. 2006). This now seems unlikely since the star-formation history in the disk has no obvious radial gradient (Lewis et al. 2015), and the cause of the ring remains a mystery.

An iconic naked-eye object, Andromeda has now been observed by professional astronomers for over a thousand years. It was discovered, or at least first mentioned, in 964 by the Persian astronomer Abd al Rahman al-Sufi (Book of Fixed Stars). In the eighteenth century, it was
observed by William Herschel, who noticed the red colors of the central bulge (Herschel 1785). In the twentieth century, Edwin Hubble used the Cepheid variables in the Andromeda Nebula to show that the nebula is actually a galaxy (Hubble 1929). In the modern era, Andromeda has been surveyed by virtually every modern observatory. A very incomplete list of the telescopes that have surveyed Andromeda includes XMM-Newton which surveyed the galaxy in X-ray (Stieble et al. 2011), GALEX in the ultraviolet (UV, Thilker et al. 2005), Spitzer in the mid- and far-infrared (Barnby et al. 2006; Gordon et al. 2006), Herschel in the far-infrared and submillimeter (Fritz et al. 2012; Smith et al. 2012; Draine et al. 2014), Westerbork & the Very Large array (VLA) in the radio 21 cm line (Braun et al. 2009; Koch et al. 2021), and the IRAM 30 meter telescope in the CO(J=1–0) line (Nieten et al. 2006). The northern third of the galaxy has also been observed with Hubble in the Panchromatic Hubble Andromeda Treasury Survey (PHAT), which detected \( \sim 117 \) million stars (Dalcanton et al. 2012).

A glaring omission on the list is a submillimeter telescope on the ground, from where it is possible to get much better angular resolution than is possible with the small mirrors of space telescopes. The angular resolution of the Herschel observations of Andromeda at 500\( \mu \)m was 36 arcsec (FWHM), which is equivalent at the distance of Andromeda (780 kpc, de Grijs & Bono 2014) to a spatial resolution of about 136 pc, roughly the size of an association of giant molecular clouds (GMCs). But with the SCUBA-2 camera on the James Clerk Maxwell Telescope (JCMT), the world’s largest submm telescope, it should be possible to map Andromeda at 450\( \mu \)m with a resolution of \( \lesssim 8 \) arcsec, equivalent to a spatial resolution of \( \lesssim 30 \) pc, slightly less than the size of a typical GMC. The reason that such a map has not previously been created is due to the atmospheric noise in the submillimeter waveband, which requires the data to be filtered strongly on angular sizes larger than that of the field-of-view of the camera, which is 45 arcmin\(^2\) in the case of SCUBA-2 (Holland et al. 2013), much smaller than the \( 3 \times 1 \) deg\(^2\) (\( \sim 10^4 \) arcmin\(^2\)) that Andromeda occupies on the sky.

The solution to the problem is to combine data from a space observatory with data from a camera on the ground, using the camera on the ground to produce the high-resolution information and the observatory in space to determine the large-scale structure. In Fourier terms, we use the space data, from Herschel and Planck to provide the low-\( k \) Fourier components and the camera on the ground to provide the high-\( k \) components.

We are using this technique to carry out a large survey of Andromeda with the JCMT: The HARP and SCUBA-2 High Resolution Terahertz Andromeda Galaxy Survey (henceforth HASHTAG). HASHTAG has been awarded 276 hours on the telescope, most of which is being used to carry out a survey with SCUBA-2 at 450 and 850\( \mu \)m (221/275 hours). The rest of the time has been used to carry out a survey in the CO(J=3–2) line with HARP in 12 regions covering a total area of 60 arcmin\(^2\) within Andromeda’s disk. By combining the data from SCUBA-2 with the Herschel images of Andromeda at six wavelengths, using an algorithm that does not require any smoothing of the data or assumptions about the temperature of the dust (Marsh et al. 2015), our goal is to produce maps of the bolometric dust emission and of the dust column density as a function of dust temperature and dust emissivity index (\( \beta \)) with a resolution of \( \lesssim 25 \) pc at \( \lesssim 70,000 \) independent positions within the galaxy — maps that will be used for a large range of scientific projects.

The CO part of HASHTAG has been completed and the results published in Li et al. (2020). The continuum part of HASHTAG is now about 70% complete and we have recently made the first full mosaics. The images cover the entire galaxy and have reached full sensitivity in the one third of the disk that has been covered by Hubble by PHAT (Dalcanton et al. 2012), by the Combined Array for Research in Millimeter wave Astronomy in the CO(J=1–0) line (Caldu-Primo & Schruba 2016), and by higher-resolution (\( \sim 10'' \)) VLA HI observations (Koch et al. 2021). By using the Herschel image at 500\( \mu \)m (Fritz et al. 2012) and the Planck image at 850\( \mu \)m (Planck Collaboration et al. 2015) to fill in the low-frequency (low-\( k \)) Fourier components, we have produced the first high-fidelity images of Andromeda from the ground, at two wavelengths, 450 and 850\( \mu \)m (Figure 1). These images are being used in the first round of HASHTAG science papers.

This paper gives an overview of HASHTAG and describes the observations and data reduction procedure used to generate the images shown in Figure 1, including a description of the technique we have developed to combine the space-based and ground-based continuum submillimeter observations, and the measures we have taken to optimize the pipeline parameters. All data products and codes presented here are available on the HASHTAG website\(^1\). Future data releases will also be made available on this site.

The organization of the paper is as follows. Section 2 gives an overview of the science program that can be carried out with these images. Section 3 describes the

\(^1\) https://hashtag.astro.cf.ac.uk/
observing method and mapping strategy. Section 4 describes the data-reduction pipeline and the method used to combine the space-based and ground-based data. Sections 5 and 6 describes the extensive simulations that we have carried out to optimize and test the data-reduction pipeline and combination method described in Section 4. Section 7 presents our final reduced maps, including some simple analysis of their properties. Finally, Section 8 describes how we estimate the contamination from CO($J=3–2$) in our continuum observations.

2. OVERVIEW OF SCIENCE PROGRAM

In this section we give a brief overview of the scientific projects that will be possible with the HASHTAG dataset. These mostly fall into two categories: dust and star formation.

2.1. Dust

Dust itself is interesting for two main reasons. First, it is of great intrinsic interest because it is a vital phase of the interstellar medium (ISM), containing half the heavy metals (James et al. 2002) and being a catalyst in the networks of chemical reactions in the ISM, including the vital one in which atomic hydrogen is transformed into molecular hydrogen. Second, mapping the continuum emission from dust grains is a promising method for both mapping the ISM in galaxies and estimating the total mass of the ISM (Hildebrand 1983; Eales et al. 2012; Magdis et al. 2012; Scoville et al. 2014). The standard tracer of the molecular phase, the CO molecule, has many well-known disadvantages (Bolatto et al. 2013). There is also now the more fundamental problem that one third of the molecular gas in the Galaxy appears to contain no CO (Abdo et al. 2010; Planck Collaboration et al. 2011; Pineda et al. 2013), and there are even galaxies in which the fraction of ‘CO-dark’ gas seems to be close to 100% (Dunne et al. 2021). Some of the advantages of using dust grains rather than CO molecules to trace the ISM are that the dust emission is optically thin, dust grains are robust and not liable to be destroyed by starlight, and the relationship between the gas-to-dust ratio and metallicity seems to be much simpler than that between CO abundance and metallicity (Eales et al. 2012; Sandstrom et al. 2013; Rémy-Ruyer et al. 2014).

The biggest contribution that HASHTAG seems likely to make to our understanding of the dust itself is to show how the properties of dust vary within an individual galaxy. The earlier Herschel observations of Andromeda revealed systematic large-scale spatial variation in the properties of dust. The emission from interstellar dust follows a modified blackbody ($S_\nu \propto B_\nu(T_d)\nu^\beta$). The Herschel observations revealed that $\beta$ varies radially within Andromeda’s disk (Smith et al. 2012; Draine

![Figure 1. The HASHTAG images created from the first ∼70% of the final SCUBA-2 dataset. The 450 and 850µm images have been smoothed with a 7.9, and 13′′ FWHM Gaussian, respectively. For the raw-resolution images see Figure 16.](image-url)
et al. 2014; Whitworth et al. 2019), and radial variation in $\beta$ has subsequently been found in the Galaxy (Planck Collaboration et al. 2014a), in M33 (Tabatabaei et al. 2014) and in $\simeq$20 other galaxies (Hunt et al. 2015), although the form of the radial variation varies between galaxies (Hunt et al. 2015). There is also now some evidence that the global value of $\beta$ varies between galaxies (Lamperti et al. 2019). The variation must be caused by changes in the structure, physics, or chemistry of the dust, although what the key changes are is currently unknown. One clue may be that in Andromeda $\beta$ does not appear to differ between low-density and high-density gas (Athikkat-Eknath et al. 2021).

HASHTAG will produce measurements of $\beta$ at $\simeq$70,000 positions in Andromeda’s disk, effectively producing a dust atlas for Andromeda. The Hubble observations of one third of the disk have produced estimates, from the optical extinction, of the column-density of dust with the same spatial resolution that HASHTAG will provide (Dalcanton et al. 2012). The combination of measurements of the emission properties of dust from submm observations and the absorption properties of dust from optical observations is a powerful one for testing theoretical dust models. The emission and absorption properties of dust, derived from Hubble and Herschel data, are already inconsistent with all existing dust models (Whitworth et al. 2019). The combination of the high-resolution measurements of $\beta$ from HASHTAG, the Hubble dust measurements, and the maps of the ISM phases, star formation, chemical abundances, and other properties that are available for Andromeda offers at least the prospect of uncovering the physical/chemical causes of the variation in dust.

The use of the dust emission to trace the ISM in Andromeda offers a number of interesting possibilities. By comparing the dust emission to the CO and HI emission it will be possible to search for CO-dark gas in Andromeda (Planck Collaboration et al. 2011; Sandstrom et al. 2013). It will also be possible to produce catalogs of GMCs based on dust emission rather than CO. This technique has already been applied to the Herschel observations of Andromeda, producing a catalogue of 326 clouds with masses between $10^4 M_\odot$ and $10^7 M_\odot$ (Kirk et al. 2015). A more recent study suggests that clouds found by the dust method have a much lower CO-to-dust ratio than the clouds found from their CO emission (Athikkat-Eknath et al. 2021), suggesting there is much more variation in the properties of clouds than one would expect from a CO-selected catalog. The clouds in the Herschel catalog are probably associations of GMCs rather than single GMCs, but with the extra resolution of HASHTAG it will be possible for the first time to produce a catalog of dust-selected clouds that are likely to be GMCs rather than GMC associations.

2.2. Star Formation

One of the most important properties to measure within a galaxy is the star-formation rate, but there is still no gold-standard way of doing this. There are at least 12 different methods, which use different techniques for tracing the obscured and unobscured star formation (Kennicutt & Evans 2012; Speagle et al. 2014; Davies et al. 2016), all of which have limitations, and none is clearly better than the others.

HASHTAG will produce high-resolution maps of the bolometric dust emission, which is a direct measurement of the emission from the obscured OB stars, although it is really an upper limit since much of the bolometric dust emission is re-radiated emission from the older stellar population (Bendo et al. 2012; Kennicutt & Evans 2012; Bendo et al. 2015; Viaene et al. 2017; Ford et al. 2013). However, since Andromeda is close enough for us to detect individual stars, there is at least the possibility of combining Hubble observations of the unobscured OB stars and the HASHTAG observations of the emission from the obscured stars to provide a direct measurement of the star-formation rate, rather than the measurements produced by the current methods, which mostly rely on indirect tracers of the star formation. The PHAT team made a first attempt to do this (Lewis et al. 2017), using optical extinction measurements to correct for obscuration, but their method was unable to account for the OB stars that are still deep in GMCs and are completely hidden by dust. If it is possible to correct for the part of the bolometric dust emission that is re-radiated emission from the older stellar population, HASHTAG will provide estimates of numbers of these missing OB stars.

3. SURVEY STRATEGY

HASHTAG is a JCMT Large Program (ID: M17BL005), and is split into two components: the continuum submillimeter observations of the entire galaxy and observations in the CO($J=3$–2) line of selected regions.

We used 55.3 hours with HARP (Buckle et al. 2009) to observe 11 $2^\prime\times2^\prime$ fields and one $4^\prime\times4^\prime$ field. We selected these fields to cover a range of diverse ISM conditions in M31 and to maximize overlap with useful ancillary data, e.g., Herschel far-infrared spectroscopy (Kapala et al. 2015). Our observations were carried out in 2017 using grade-3 weather, defined as when the opacity at 225 GHz ($\tau_{225\ \text{GHz}}$) is between 0.08 and 0.12, and reached a sensitivity of $\simeq$ 15 mK (antenna temperature, $T_A$) with an angular resolution of 15$''$ and spectral resolution of...
The SCUBA-2 Pong observing mode is used for sources (P.I. Smith) and was effectively HASHTAG’s pilot field. The larger component of HASHTAG consists of the continuum observations, which were allocated 221 hours in the less-common grade-2 weather (0.05 < τ_{225 GHz} < −0.12) and commenced in 2017 (expected to complete 2021). SCUBA-2 observes simultaneously at 450 and 850 μm, producing images at the two wavelengths with the same field-of-view (Holland et al. 2013) and angular resolutions of 7.9 and 13.0″ at 450 and 850 μm, respectively (Dempsey et al. 2013). Our goal was to observe the entire galaxy at both wavelengths.

Our continuum observing strategy is based on our experience in a smaller project in 2015 (project M15BI082, P.I. Smith) and was effectively HASHTAG’s pilot field. For the pilot we made a long Pong exposure of a single circular region of diameter 15, 30 or 60 arcmin (since the design of HASHTAG a 45 arcmin mode has been added). For this field, we chose the position of the center so that this circular region would also include a significant area in which there was no obvious sub-millimeter emission in the Herschel images from the galaxy itself, since we knew this ‘background region’ would help the data reduction to converge. The maximum integration time for a SCUBA-2 observation is 45 minutes. We chose an integration time of 43 minutes, repeating it 37 times. We reached a sensitivity of 44.9 and 3.0 mJy beam⁻¹ using 2.0 and 4.0″ pixels, at 450 and 850 μm, respectively.

Given the success of these observations, and our development of a technique to use space-telescope data to replace the large-scale structure severely suppressed by the filtering necessary to remove atmospheric noise (see Sections 4 and 5), we realized it would be practical to use a similar strategy to observe the whole of Andromeda. We continued to use the 30-arcmin Pongs, choosing the center of each field so that the field contained a similar amount of blank sky to the pilot field. This decision required us to have two rows of Pongs along the major axis. To achieve fairly uniform sensitivity we chose the positions of the centers so the circles overlapped, as is shown in Figure 2. At each position we made 17 repeat observations of 43 minutes each. Since each position in the galaxy will be covered by at least two Pongs, every point in the galaxy will be observed, when the survey is complete, at least 34 times, with a total integration time of 24.4 hours per 30 arcmin diameter region, the same as the pilot survey. We also include data from two significantly shallower projects (M12BU26 & M13BU18) that also observed the entirety of M31.

There are two advantages of the design of the fields shown in Figure 2. There is a very large amount of overlap in the observations, especially as the area covered by a Pong is somewhat larger than the nominal 30-arcmin circle. This overlap and redundancy in the data is a considerable help in the data reduction, in particular for distinguishing real emission from atmospheric emission. The second advantage is that the two rows of Pongs overlap, so the sensitivity of the survey will be much greater along the major axis of the galaxy, which helpfully covers the central regions of Andromeda where the dust emission is much weaker than in the star-forming ring.
Inspired by the discovery of luminous transients in the mid-infrared (Kasliwal et al. 2017), one of our science goals is to determine whether there are any luminous transient sources in the submillimeter waveband. We have therefore split our 17 observations in each field into two sets of 9 and 8 observations, with the aim of eventually producing two images of Andromeda separated in time, so we can search for transient phenomena. We have tried to prioritize our observations to ensure that there is at least a six-month gap between the two sets for each field, but due to the vagaries of the weather and the flexible observing queue at the JCMT, it is impossible to do this perfectly. However, we do achieve some time cadence in the observations, which we will investigate in future works.

4. DATA REDUCTION: 1. THE METHOD

Big sub-millimeter datasets can be challenging to reduce, but HASHTAG is particularly difficult. Large cosmology programs, for example, produce datasets as large as ours but they have the advantage that the data can be reduced piecemeal; the individual datasets are reduced separately and then the images added together. We were not able to follow this approach because we want to maximize our sensitivity to extended low signal-to-noise emission, which required us to reduce all the data together.

In this section we describe the elements of our method. In Sections 5 and 6 we describe the sky simulations we carried out to optimize the method. Unless stated otherwise, the methods we used for the observations and for the data reduction are the standard ones used for SCUBA-2 (Dempsey et al. 2013; Chapin et al. 2013).

4.1. Initial Processing and Quality Review

As soon as one of our observations was made, we processed it using a quick-look script that produced images at the two wavelengths (450 and 850µm) and saved the cleaned data from the individual bolometers. We used these images to check for any severe problems (e.g., array failures or low sensitivity), which for SCUBA-2 data is extremely rare (only 2 out of 235 observations had issues). We used the saved bolometer data from this initial processing as the input for the next stage, which resulted in a considerable rationalization of the data, since the initial processing converted the hundreds of raw-data files into just eight (one per array).

4.2. An adaptable skyloop: scubaDuperSkyloop

To reduce SCUBA-2 data, the observatory provides an iterative data-reduction procedure called MAKEMAP, which at the end of every iteration provides a better estimate of the astronomical signal and the noise until no further improvement is made. Here we provide a brief summary of the MAKEMAP algorithm but refer the reader to Chapin et al. (2013) for full details. MAKEMAP is provided as part of the STARLINK software package (Currie et al. 2014) and throughout this paper we use a recent development build of STARLINK (version 9072c4434 from April 2020), because we required some updates since the last 2018A stable release.

Initially MAKEMAP splits the raw data into individual observations (sub-divided into chunks if enough RAM is not available, although for HASHTAG ‘chunking’ was not required). There is an initial cleaning step for each observation in which bad bolometers are masked and artifacts (e.g. glitches) are removed from the timelines. MAKEMAP then starts the iterative process. At the beginning of each iteration, the common-mode signal (common to all bolometers) is removed. The data are then corrected for atmospheric extinction, and a high-pass filter is applied to the timeline data to remove any residual, slowly varying signal. Since in the SCUBA-2 arrays are moving across the sky, the removal of a slowly varying signal is equivalent to removing emission on a large angular scale. An image is then made from the data. Any real astronomical signal is then identified in the image, and this astronomical signal is then removed from the timelines (an optional signal-to-noise cut or mask can be applied). The process is then repeated on the new timeline data, with the astronomical signal being updated in each iteration. The process stops when the pixel variations in the map at the end of each iteration fall below a set threshold (i.e., when the map has ‘converged’). If we had used the standard implementation of MAKEMAP, our final image of Andromeda would have been a mosaic of the images made by MAKEMAP from each individual observation.

However, a weakness of MAKEMAP is that a single ∼43 minute Pong observation does not have the sensitivity to detect the low-surface-brightness emission in Andromeda’s disk. Recognising this limitation, the STARLINK team created a script called SKYLOOP\(^2\), which runs MAKEMAP on all the observations, one iteration at a time, combining the individual images at the end of each iteration to produce the best estimate of the astronomical signal, thus maximizing the signal-to-noise ratio in the faint extended structure. However, the volume of our data is so large that SKYLOOP would take too long to run. We built on our previous work (Smith et al. 2019) to develop a new version of SKYLOOP that we

\(^2\) https://starlink.eao.hawaii.edu/docs/sun258.htx/sun258ss72.html
nicknamed ‘scubaDuperSkyloop’. The main difference from the old script is that while SKYLOOP is given all the observations and internally processes them individually, mosaicking the images at the end of every iteration, our modified script calls MAKEMAP separately for each iteration and each observation. We found that the new script was more stable on our system (possibly due to more regular memory clearance); however, the main advantage of our approach is that each observation can be processed in parallel, or even on separate machines. Although MAKEMAP can process individual observations using multiple threads, there are diminishing improvements in processing time.

To make the final images shown in this paper, we reduced all the data using a new processing machine with 768 GB of RAM and 32 cores/64 threads, which allowed us to run five invocations of MAKEMAP in parallel. The main factor limiting the speed of ‘scubaDuperSkyloop’ was the speed of our hard-disk drives. We increased the speed of the simulations described in section 5 by running the script in parallel on two separate smaller machines (with common storage access).

4.3. Restoring the Large-Scale Structure

Ground-based sub-mm surveys of sources with extended emission (greater than a few arcminutes) face the challenge of slow variations both in the atmospheric emission and within the camera, which need to be removed from the data. This is overcome using harsh high-pass filtering, which also removes real astronomical signal on large angular scales. However, there are sub-millimeter observations of many objects with the space telescopes Planck and Herschel. The images made with these telescopes do preserve the large-scale structure; however, because of the small sizes of the telescopes’ mirrors they do not have as good resolution as images made with telescopes on the ground. In principle, we can now produce high-fidelity images of submillimeter sources with large angular sizes by combining observations with telescopes on the ground, which provide the small-scale structure, with observations made with telescopes in space, which provide the missing large-scale structure. This technique has often been used in radio astronomy to combine single-dish and interferometer measurements; as the latter sparsely samples the UV plane, the case here is potentially simpler.

We have produced the high-fidelity image of Andromeda at 850µm by combining the SCUBA-2 image at 850µm and the Planck image at 353 GHz, which is virtually the same wavelength. At 450µm, we have combined the SCUBA-2 image at this wavelength with the Herschel image at 500µm (Smith et al. 2012). To combine the low- and high-resolution images we have written a Python module that applies a ‘feathering’ technique (Bajaja & van Albada 1979). The module performs the following steps:

1. The low-resolution FITS image is re-projected so that the pixel scale and the celestial coordinates of the pixels are the same as in the high-resolution image. The units of both images are converted into Jy beam$^{-1}$ using information contained in the header or supplied by the user.

2. We apply color-corrections to the high and low-resolution images to correct for the effect of different instrumental filters, calibration schemes (e.g., different reference spectra), and differing central frequencies. To apply this correction the user can specify a fixed dust temperature and $\beta$, provide maps of the dust parameters, or a cube generated with the surface-density of dust for a grid of dust temperatures and $\beta$‘s. A pre-computed grid specific to each far-infrared/sub-millimeter instrument is used to perform the corrections, and is provided with the task.

3. The median value in each image is subtracted from the image and ‘NaN’ pixels are replaced with zeros to avoid artifacts.

4. Both images are Fourier transformed and shifted so a spatial frequency of zero is assigned to the center. The values in the Fourier Transform (FT) of the low-resolution image are scaled by the ratio of the beam areas of the high-resolution and low-resolution images.

5. A filter is then created to weight the FT images by the selected amount when they are combined. The standard filter in the module, which we used for HASHTAG, is a Gaussian filter in Fourier space. We chose the value of the filter’s standard deviation using the simulations described in the next section. The FT of the high-resolution image is multiplied by one minus the Gaussian filter. The FT of the low-resolution image by default is not weighted, because the image is effectively already weighted by the point spread function of the image; this is the same method employed by CASA (McMullin et al. 2007). In our simulations we also try the alternative where the low-resolution FT image is weighted by the Gaussian filter, which is applicable when the filter is on significantly larger spatial scales than the resolution of the images. For a full discussion of combining images in the Fourier plane see Stanimirovic (2002).
The weighted FT images are then added together. There is also an option in the module to use either a Butterworth filter (Csengeri et al. 2016) or sigmoid filter, in which case both FTs are multiplied by the filter. We tried these filters for HASHTAG but found they did not produce appreciable benefit over the Gaussian filter.

6. The combined FT image is then inverse Fourier transformed (with appropriate inverse shifts applied). The NaN pixels are restored, the median background from the original low-resolution image is added back to the new image, and the keywords in the image header are updated\(^3\).

7. As many spectral energy distribution (SED) fitting procedures apply a color-correction step in their processing, we remove the color corrections performed in step 2, so the flux densities in the final images are based on the same assumptions as regular SCUBA-2 images.

One key parameter in the ‘feathering’ algorithm is the scale of the Gaussian filter. As the feathering step is a relatively quick process (compared to the SCUBA-2 pipeline) we keep this as a free parameter, which we optimize in Section 5 and 6. For the color corrections we assume the SED in each pixel estimated by Whitworth et al. (2019), who applied the PPMAP algorithm to the Herschel dataset to generate SEDs with the angular resolution of the highest resolution Herschel image. For the Herschel and Planck images, we calculated the color corrections using these SEDs and the filter curves available on the observatories’ websites, after removing the standard SED used to estimate the Planck and Herschel flux densities \(F_\nu \propto \nu^{-1}\). SCUBA-2 flux densities, on the other hand, are calibrated relative to Mars and Uranus, which means that they are based on a very different assumption about SEDs (roughly \(F_\nu \propto \nu^{1.7}\), Lellouch & Amri 2008; Orton et al. 2014). We calculated the color corrections for the SCUBA-2 images after removing this assumption and then using the PPMAP SED in each pixel. For SCUBA-2, an additional complication is that the effective filter function is the product of the actual filter function and the atmospheric transmission. We calculated the effective filter function from the filter function available on the observatory’s website and a model for the transmission of the atmosphere\(^4\) with \(\tau_{225\text{GHz}} = 0.065\) to match the weather for our survey. The color corrections are small (\(\leq 3\%\)) for the two SCUBA-2 filters and for the Herschel 500µm filter, apart from the large correction needed to change the flux at 500µm to one at 450µm, which ranges from a factor of \(\sim 1.5\) in the center to \(\sim 1.34\) in the ring. The color correction for the Planck filter is \(\sim 10\%\).

Figure 3 shows the results of the feathering technique when applied to SCUBA-2 simulation (see Section 5), illustrating how it is effective at restoring the structure on all spatial scales. The red line shows the power spectrum of a simulated ‘true’ image of the sky at 850µm (with artificial noise added to match the SCUBA-2 image). The green line shows the power spectrum of what Planck should see, obtained by convolving the true image to the Planck resolution. The blue line shows what SCUBA-2 should see, obtained by passing the true image through the SCUBA-2 data-reduction pipeline. As expected, the Planck spectrum is missing the high-\(k\) Fourier components and the SCUBA-2 spectrum the low-\(k\) Fourier components. The orange line shows the power spectrum of our reconstruction of the sky by applying our feathering technique to the artificial Planck and SCUBA-2 images. For reference the location of the half-width at half-maximum (HWHM) for SCUBA-2 and Planck is shown by the gray vertical lines. Note that in all cases we have restricted the images to the central 30’ region.

\(^3\) There is an option in the module to add back a background by calculating the offset between the original low-resolution image and the new image smoothed to the same resolution.

\(^4\) Atmospheric model from from the Caltech Submillimeter Observatory (Pardo et al. 2001), http://www.submm.caltech.edu/cso/weather/atplot.shtml.
ing the high-$k$ and in the other case the low-$k$ Fourier components. The orange line shows the power spectrum of our reconstruction of the sky by applying our feathering technique to the artificial Planck and SCUBA-2 images.

We performed a sanity-check of the method by applying it to a Herschel 250µm image of the Milky Way (Molimari et al. 2016), in which the large-scale emission is detected with high signal-to-noise ratio. We created an artificial image at the Planck resolution by smoothing the Herschel image, and we created a rough simulation of what a camera such as SCUBA-2 would see by using the NEBULISER algorithm developed by the Cambridge Astronomical Survey Unit\(^5\) to remove the structure on large scales. When we produced our combined image by applying our feathering technique to the two artificial images, we found a good agreement with the original image (to within a few percent), although in the brightest regions there were differences up to the 10% level.

There are also some parameters to tune in MAKEMAP, in particular the scale of the high-pass filter used to remove the signal from the atmosphere and the camera itself. To produce a reliable map of Andromeda it is crucial to get these values right. This is a particular challenge at the longer of the two SCUBA-2 wavelengths because of the need to ensure that emission on the SCUBA-2 images is preserved on all angular scales up to the angular resolution of Planck (≃5 arcmin, FWHM). In the next section, we describe the simulations of the sky that we used to determine the best values of the parameters.

5. THE SIMULATIONS AT 850µm

We carried out simulations of the sky to optimize the data-reduction procedure described in the previous section. The SCUBA-2 pipeline has many parameters that can be tweaked to optimize the reduction process depending on the angular extent of the source, the observing strategy, and the atmospheric conditions. Two of the big unknowns are the scale of the Gaussian filter used in combining the low- and high-resolution data and the angular scale of the high-pass filter that should be used in the SCUBA-2 data reduction to remove the noise on large angular scales caused by the atmosphere and the camera. Too harsh a filter would remove the noise but also remove too much astronomical signal, too weak a filter would leave the astronomical signal alone but not remove the noise. In this section we create a ‘simulation’ to test the effects of the various pipeline parameters so we can obtain the most accurate map of M31’s sub-millimeter emission. In this process we have restricted ourselves to the SCUBA-2 pipeline, rather than attempt alternative methods (e.g., SCANAMORPHOS, Roussel 2013) or complex atmospheric modeling.

An outline of our method is as follows. (1) We used real SCUBA-2 data from a cosmology Large Program with similar noise properties to our own dataset. (2) We then created a ‘true’ image of Andromeda from a Herschel image and inserted this into the timelines for the cosmology program. (3) We convolved the true image to produce an artificial Planck image. (4) We ran the SCUBA-2 dataset (cosmology timelines injected with our model galaxy) through the SCUBA-2 data-reduction pipeline (Section 4.2). (5) We combined the reduced SCUBA-2 image and the Planck image to try to recover the original image using the method of Section 4.3. (6) We measured the statistical differences between our recovered image of Andromeda and the original true image. We ran thousands of simulations, trying different variants of the SCUBA-2 data-reduction pipeline, in particular trying different values of the scale of the high-pass filter, and trying a range of values for the scale of the Gaussian filter used to combine the low-resolution and high-resolution data (Section 4.3). In this section we describe the simulations at 850µm, which were more critical because Planck at 850µm has a much lower resolution than Herschel at 500µm. We describe what we did for the 450µm data in Section 6.

5.1. Simulation Setup

We chose to carry out a simulation of a single 30′ Pong observation with a similar sensitivity to our pilot field. While ideally we would have simulated observations of the whole galaxy, the processing time would have been too long and there was no suitable SCUBA-2 data we could use for a simulation of the entire galaxy at our depth. For our simulation we used data from the SCUBA-2 Cosmology Legacy Survey (Geach et al. 2017). We chose to use the data from the survey of the Lockman Hole because it was carried out in similar weather conditions and consisted of 35 30′ Pongs, the same as we used in our observations of our pilot field (Section 3), reaching a similar sensitivity.

We made our ‘true’ image out of the Herschel 250µm image, which has a resolution (18 arcsec, FWHM) that is not very different from that of SCUBA-2 at 850µm (13.5 arcsec, FWHM). We first reprojected the Herschel image onto a 4″ pixel grid and then multiplied the intensity values in each pixel by the ratio of the global 250µm and 850µm fluxes (Planck Collaboration et al. 2015). The Lockman-Hole data are actually slightly less sensitive than the data for our pilot field (3.4 versus

\(^5\) http://casu.ast.cam.ac.uk/surveys-projects/software-release/background-filtering
3.0 mJy beam$^{-1}$), so to make the signal-to-noise ratio of our artificial image the same we multiplied the intensity values by the ratio of the noises. We also applied color corrections. We then converted the intensity values into instrumental units of picowatts (pW) and ran makeMap with the options “fakemap” and “exportclean” set so that our artificial 850 $\mu$m image was added to the SCUBA-2 timelines for the Lockman Hole survey. We used the data files exported by this process, which also did the initial cleaning of the timelines, to carry out our simulations. We produced our artificial Planck image by convolving our input image to the Planck resolution.

We performed five different sets of simulations, to optimize different aspects of the method. While in an ideal world every possible combination of parameters in the SCUBA-2 data-reduction pipeline would be tested, each individual simulation required ~8–10 hours to run. Therefore, we varied one parameter at a time. However, our reconstruction process in which we combined the processed SCUBA-2 image with our artificial Planck image was quite quick to run, so at the end of every run of the pipeline, we applied our reconstruction technique many times, each time with a different value for the scale of the Gaussian filter, with scales ranging from 160 to 840$''$.

We measured the success of a simulation by the differences between our final image and the original true image. We assessed the significance of the differences using the noise image produced by the pipeline, but since changes to the pipeline also change the noise in the final image we also used a reference noise image (from a run using typical values of all the pipeline parameters). For each final SCUBA-2 image, we created several ‘difference maps’ of the difference between the image and the true image: (1) a basic residual image, i.e., the final image minus the ‘true’ image; (2) the residual image divided by the noise image; (3) the residual image divided by the reference noise image; (4) the residual image divided by the true image.

To assess the agreement, we measured statistics in two different regions of these difference maps: (1) the full-depth region of the Pong; (2) the full-depth region of the Pong but only for pixels where the flux in the pixel in the Herschel 500 $\mu$m image is above a critical value (500$\mu$m is used as its closest in wavelengths to both SCUBA-2 bands). The point of the second region was to stop the more numerous pixels outside the galaxy with little emission biasing the results, because a method producing a flat map (e.g., harsh Fourier filtering) would be preferred. We inspected all of these methods of assessing the agreement at one time or another. The statistic that we found most useful was the mean of the absolute difference between the final image and the true image divided by the reference noise image, for pixels in the deep region above the 500$\mu$m threshold. This statistic using a reference noise map has the advantage that changes in the noise map do not bias the estimate of how well we recover the galaxy, while still accounting for variations in the sensitivity across the map.

### 5.2. Filter-scale and PCA-components

The most important parameter in the SCUBA-2 data-reduction pipeline is the scale of the high-pass filter used to remove residual emission from the atmosphere or the instrument. We started our simulations with the expectation that we would need to set the scale to roughly the angular resolution of Planck. In our early results we found that with a filter scale of 340$''$ we were able to reproduce the true image well.

In April 2019, however, the observatory released a new mode for the SCUBA-2 pipeline in which principal component analysis (PCA) is used to remove residual atmospheric and instrumental noise. The advantage of PCA is that it makes it possible to increase the angular scale of the high-pass filter, reducing the attenuation of the emission on the SCUBA-2 images on large angular scales. Of course, if one allows PCA to remove too many components, it is also possible to remove real astronomical emission from the image. In the SCUBA-2 pipeline the default number of PCA components to remove is 20 components per sub-array, but after inspecting the final images made with this setting we decided it led to the removal of some real emission. We therefore decided to run a suite of simulations in which we varied both the scale of the high-pass filter and the number of PCA components.

In our initial simulations without PCA we had found an optimum filter scale of 340 arcsec. We realized that with PCA we should be able to increase this scale. We therefore ran simulations with filter scales between 340$''$ and 560$''$ and the number of PCA components between 0 and 20, running 91 simulations to cover this 2D parameter space (20 PCA components is the default in the new pipeline mode).

Figure 4 shows the effect of changing the number of PCA components while keeping a constant filter scale of 520 arcsec. The top-left panel shows what happens if no PCA components are removed. The filter may not remove much large-scale emission from the galaxy but much of the emission visible in the picture is clearly spurious. Increasing the number of PCA components leads to better removal of these artifacts, but the removal of too many PCA components leads to the removal of real astronomical signal, producing the negative regions
Figure 4. Reconstructed SCUBA-2 images made with a high-pass filter in the SCUBA-2 pipeline of 520 arcsec but with different numbers of PCA components removed (0, 3, 7 and 20). The red area is the circular region with a diameter of 30′ in which the Pong reaches full sensitivity. The color scale has been chosen to enhance faint features. The removal of too few PCA components leads to large-scale artifacts in the image (top left panel); too many PCA components removes real astronomical signal, leading to the negative regions close to the bright structure (bottom right panel).

An important point to note is although the eye tells us that the patches in the top left panel in Figure 4 are artifacts, the SCUBA-2 data-reduction pipeline treats these as real emission, which means that the values in the noise image produced by the pipeline are too low. Figure 5 shows how the average noise in an image depends on the number of PCA components and on the scale of the high-pass filter. The solid lines show the results when the noise is measured from empty areas of the image and the dashed lines show when it is measured from the noise image produced by the SCUBA-2 data-reduction pipeline. The difference between the two sets of lines shows that the noise values from the variance map produced by the pipeline are unreliable because the pipeline mistakenly identifies large-scale noise as real astronomical signal and therefore underestimates the noise. Even when these artifacts are removed with a harsh high-pass filter or by removing a large number of PCA components, there is still a small difference of \( \sim 0.2 \, \text{mJy beam}^{-1} \), which is possibly caused by faint sources in the apparently empty regions of the image.

We chose the best combination of filter scale and number of PCA components based on a combination of visual inspection of the residual maps and the statistical estimates of the difference between the recovered image and the true image. Figure 6 shows the mean absolute residual for the difference map made by dividing the residual image by the reference noise image (number three in Section 5.1). The statistic has been calculated for the pixels that are in the full-depth region and are above the 500 \( \mu \text{m} \) threshold value (see above). The figure shows that there is an advantage in increasing the scale of the high-pass filter from the 340 arcsec that we had originally considered (see above) if removal of PCA components is included in the analysis. The best agreement between the recovered and true image is obtained for a filter scale of \( \sim 520 \) arcsec. The figure also shows that there is an optimum number of PCA components of \( \sim 8 \) — removing more increases the difference between the recovered and true images. Based on these results, we visually inspected the recovered images for a filter scale of 480′′ and 5 or 6 PCA components and
for a filter scale of 520″ with 7 or 8 PCA components, concluding that the best results came with a filter scale of 520″ with 7 PCA components. However, in the next stage of the simulations we also tested the method with a filter scale of 480″ and 5 PCA components, in order to check whether the optimum values shifted if other parameters in the method were varied.

In the simulations, we also checked the number of iterations in the pipeline required for each set of parameters, since the computer processing time is directly proportional to the number of iterations. We found, as expected, that there is a processing cost to setting a larger filter scale (from 8 to 19 iterations) but including PCA analysis can reduce this.

5.3. The Mask

An important element in the SCUBA-2 data-reduction pipeline is a mask provided by the user as their best guess of the area in which real astronomical signal will be found. This greatly helps the convergence of the iterative procedure because it makes it easier for the algorithm to distinguish between real astronomical emission and extended structures that are actually the result of atmospheric emission or noise in the camera (see Figures 4 & 5). This does not mean that a pixel in the final image that is not within the mask will necessarily contain no astronomical signal. The software only subtracts astronomical signal from samples in the timelines that will contribute to image pixels within the mask, but once all data-reduction stages are completed (subtraction of PCA components etc.) even pixels outside the mask, which are the averages of many samples in the timeline, may still contain astronomical signal.

The mask we used was created from the Herschel 500µm image of Andromeda (Smith et al. 2012), the Herschel image closest in wavelength to our 850µm image. We defined the mask as all pixels above a 500µm flux-density threshold, with this threshold providing another knob we could twiddle in our analysis. Too high a threshold makes it possible for the algorithm to treat real astronomical signal as noise and remove it from the timelines; too low a threshold leads to slower convergence of the algorithm and higher noise. In the simulations described in the previous section, we set the 500µm flux-density threshold at 200 mJy beam⁻¹, which seemed a reasonable compromise because the mask then included most of the disk and some inner regions of the galaxy while excluding some regions between the rings where the emission is faint.

Once we had identified the best combinations of filter scale and number of PCA components (520 arcsec and 7 PCA components or 480 arcsec and 5 PCA components), we used these to test the effect of changing the flux threshold used to construct the mask. We ran simulations with values of the 500µm flux threshold between 120 and 520 mJy beam⁻¹. Figure 7 shows masks created with a range of flux thresholds that are representative of the ones we used in the simulations. Figure 8 shows the results of the simulations. The agreement between the input and output images is clearly best for a 500µm flux-threshold of 280 mJy beam⁻¹ (this includes ~25% of the total flux of M 31), which is the threshold we adopted to create the mask for the real 850µm observations of Andromeda. We found that changing the flux threshold and thus the mask had a negligible effect on the noise of the final image, a very slight increase (< 1%) for masks generated with a 500µm flux-threshold below 200 mJy beam⁻¹.

5.4. Tolerance Level

The next parameter we investigated was the map-tolerance parameter, which the SCUBA-2 data-reduction pipeline uses to decide whether the algorithm has converged or whether more iterations are required. The default tolerance value is 0.05, which means that the iterations stop when the average change in the flux in a pixel from the last iteration is less than 0.05 σ, σ being the noise in that pixel (calculated from the distribution of instrument samples contributing to that pixel). There have, however, been some studies (Mairs et al.
Given our huge volume of data, another important consideration was processing time, which increases if the tolerance value is reduced because a greater number of iterations are then needed to reach a lower tolerance value (processing time scales linearly with number of iterations). We therefore carried out simulations over a fairly small range of tolerance values: 0.0075–0.05. In Section 5.3 we found that we achieved the best results with a mask generated with a 500µm threshold of 280 mJy beam$^{-1}$. In the simulations described in this section, we also experimented with masks created with 500µm thresholds of 200 and 240 mJy beam$^{-1}$ to see whether the choice of best mask changed if we also changed the tolerance parameter. We also tried both winner and runner-up from the competition between filter-scale/PCA combinations of Section 5.2 to see whether the order might be reversed with a different value of the tolerance parameter.

Figure 7. The grayscale image is the 500µm Herschel image that we used to create the mask used in the SCUBA-2 data-reduction pipeline. We defined the mask as all pixels with a 500µm flux density greater than a threshold value. In the simulations described in Section 5.3, we tested the effect of changing this threshold value. The five contours show the masks created from flux thresholds that are representative of the ones we used in the simulations.

Figure 8. Mean absolute residual in the difference map versus the 500µm flux-threshold used to define the mask used in the SCUBA-2 data-reduction pipeline (see the caption of Figure 6 for details of the difference map and of the region used to measure the statistic). The two lines are the results from using the best combinations of filter scale and number of PCA components identified during the simulations described in Section 5.2. The plot shows the best 500µm flux-threshold for creating a mask is 280 mJy beam$^{-1}$ for both combinations of filter scale and PCA number.

Figure 9. Mean absolute residual in the difference map versus the value of the tolerance parameter used in the SCUBA-2 data-reduction pipeline (see the caption of Figure 6 for details of the difference map and of the region used to measure the statistic). The blue lines show the results from simulations with a filter scale of 520″ and 7 PCA components, and the orange lines show the results from simulations with a filter scale of 480″ and 5 PCA components. The solid, dashed, and dotted lines show the results from simulations with a mask made with a 500µm flux threshold of 280, 240 and 200 mJy beam$^{-1}$, respectively. The plot shows that there is an improvement made by reducing the value of the tolerance parameter, but the improvement is modest, and there is a trade-off with an increase in computer processing time.
Figure 10. The mean absolute residual in the difference map versus the scale of the Gaussian filter, the ‘feather scale’, used to combine the SCUBA-2 and Planck image (see the caption of Figure 6 for details of the difference map and of the region used to measure the statistic). The two lines show the results of the simulations for our winning and runner-up combinations of high-pass filter scales in the SCUBA-2 data-reduction pipeline and number of PCA components. The plot shows we get the best results for our winning combination (520 arcsec and 7 PCA components) when we combine the SCUBA-2 and Planck images with a Gaussian filter with a scale of 320 arcsec.

Figure 9 shows that decreasing the value of the tolerance parameter does improve the agreement between the true and recovered images. It also shows that the best choices for mask and filter-scale/PCA combination generally remain the best choices at all values of the tolerance parameter. The improvement with decreasing tolerance parameter is fairly slow, and there is a high price in increased processing time. Therefore, as a trade-off, we adopted a tolerance parameter of 0.03 for the real observations. Even with this tolerance parameter, reducing the current HASHTAG 850μm dataset, which is only 70% of the final dataset, required 7.5 days of computer processing time.

5.5. Feather Scale

The final parameter we investigated was the scale of the Gaussian filter, the ‘feather scale’, used to combine the SCUBA-2 and Planck images. In this final round of simulations, we changed the pixel scale from 4.0 arcsec to 4.5 arcsec, which makes the pixels in the final 850μm image close to one third of the FWHM of the point spread function, the value that was eventually adopted after some experimentation for making Herschel images. Figure 10 shows the results from the simulations. The agreement between the ‘true’ input image and the recovered output image is best when the scale of the filter is 320″, which is roughly what we expected; the resolution of Planck is 4.8′ (290 arcsec) (Planck Collaboration et al. 2014b) and so the Planck image should supply all Fourier components on angular scales larger than this. In all the 850μm simulations the feathering method where the low-resolution image is not weighted is preferred (see Section 4.3).

5.6. The final values of the parameters

As the result of these simulations, we adopted the following values for all of the parameters when reducing the real SCUBA-2 data:

- We set the scale of the high-pass filter in the SCUBA-2 data-reduction pipeline to 520″ (flt.filt_edge_largescale=520).
- We set the number of PCA components per array in the SCUBA-2 data-reduction pipeline to 7 (PCA.PCATHRESH=-7) with the values of all the other parameters in the PCA analysis having their default values.
- We use an input mask to define the region where there is likely to be astronomical signal created from the Herschel 500μm image (Smith et al. 2012). This is used by the SCUBA-2 data-reduction pipeline (the AST model in the pipeline). We defined the mask as all pixels with a 500μm flux greater than 280 mJy beam$^{-1}$.
- We set the tolerance parameter in the SCUBA-2 data-reduction pipeline to 0.03.
- We use a pixel scale for the final 850μm image of 4.5 arcsec.
- We used a Gaussian filter with a scale (the ‘feathering scale’) of 320″ to combine the final SCUBA-2 image with the Planck image.

These pipeline parameters are optimized for the observing strategy, source properties, and weather for HASHTAG and M 31. For other SCUBA-2 datasets with extended structure, we would recommend performing a similar simulation to optimize the processing; however, these results should provide a useful initial guess.

5.7. A test of the image fidelity

The final stage in the simulations was to assess the fidelity of the final image produced with the values of the parameters listed in the previous section. How close is the structure in the final image to the structure in the original true image? This analysis gives us a useful estimate of the fidelity of our real image. Note, however, that analysis will yield an upper limit to the errors on
Given the discrepancy between the actual distribution of $D$ and its predicted distribution, we have assumed that the true uncertainty of the flux in each pixel is given by three uncertainties added in quadrature:

$$\sigma_{\text{tot}}^2 = (a)^2 + (b \sigma_{\text{pipe}})^2 + (f S_0)^2$$  \hspace{1cm} (1)$$

in which $a$ is a constant, $b$ is a multiplicative factor for the error given by the SCUBA-2 data-reduction pipeline ($\sigma_{\text{pipe}}$), and $f$ is a multiplicative factor for the flux in the output image ($S_0$). The third error in Equation 1 is effectively a photometric calibration error, which exists for all astronomical observations, although in this case it is an error on top of the standard SCUBA-2 photometric calibration error, which we have not included in the equation. We estimated the values of $a$, $b$, and $f$ by applying the minimization package lmfit (Newville et al. 2016) so that the standard deviation of $D$ approached as closely as possible a value of 1. We carried out the minimization on a rolling group of 800 pixels ranked in flux. We found $a = 0$, $b = 1.04$, showing the SCUBA-2 data-reduction pipeline had slightly underestimated the random errors in the fluxes, and that $f = 0.12$, showing that there is a systematic error that depends on the brightness of the emission, confirming the qualitative impression produced by Figure 11.

The bottom-panel of Figure 12 shows the same surface-density plot of pixels as the top panel but with the noise value predicted by the pipeline ($\sigma_{\text{pipe}}$) replaced by the noise value calculated from Equation 1 ($\sigma_{\text{tot}}$). The distribution shows that while the width of the distribution of $D$ now is roughly correct, the distribution is still distorted, in the sense that as the output flux density ($F_o$) increases, the output flux density becomes progressively higher than the input flux density ($F_i$), although there is a suggestion above 30 mJy beam$^{-1}$ that this reduces. We could have corrected the flux densities in the real HASHTAG image using the red curve in the bottom panel of the figure. We decided not to do this for two reasons. First, the real HASHTAG image is made
Figure 12. A surface-density plot showing how the number of pixels depends on $D$ and the input 'true' flux in a pixel. $D$ is the difference between the flux density in a pixel in the recovered image and the flux density in the true image divided by the noise in that pixel. The distribution has been renormalized, column by column, so that the figure is not dominated by the number of pixels with faint flux densities. The top panel shows the distribution if the noise that is used is the noise produced by the SCUBA-2 pipeline. The red and cyan lines are the rolling (800 pixels) mean and $\pm 1\sigma$ standard deviation, respectively. For a perfect observation the red line would follow a mean of zero (black line) and the standard deviation lines would follow the gray lines at $\pm 1$. The green vertical lines show the average $1\sigma$ noise in the true image. The bottom panel shows the same distribution when the noise has been rescaled using the method described in the text.

Figure 13. The same plot as Figure 5, but for 450\,µm data rather than at 850\,µm. Increasing the number of PCA components leads to a significant reduction in the noise measured in the image.

Figure 14. The same plot as Figure 6, but for 450\,µm data rather than at 850\,µm. See the caption of the earlier figure for details.

components of the space-based and SCUBA-2 observations are therefore much closer than at the long wavelength. Nevertheless, we performed the same set of simulations as at 850\,µm, and we summarize the results in this section.

Figure 13 shows how the noise in the 450\,µm image varies with the filter-scale and the number of principal components used in the reduction. The number of PCA components is found to be particularly important, with the noise changing from $\sim 60$ to $\sim 45$ mJy beam$^{-1}$ with increasing number of PCA components. As before, we investigated the effect on the mean absolute residual in the difference map of changing the filter scale in the pipeline and the number of PCA components. We tried filter scales between 120$''$ and 480$''$, with the lower bound chosen because it is used by the Cosmology Legacy Survey (Geach et al. 2013) which was optimized

6. THE SIMULATIONS AT 450µm

Optimizing our data-reduction was much simpler at 450\,µm than at 850\,µm because at the shorter wavelength the space-based image has structure down to a much smaller angular scale ($Herschel$ — 36 arcsec) than at 850\,µm ($Planck$ — 5 arcmin). The ranges of Fourier

of a large number of spatially overlapping datasets, so it is possible this effect is less for the real image. Second, this systematic effect is fairly small compared with the statistical error: only $0.6\sigma$ at $F_o = 21$ mJy beam$^{-1}$.
for detecting point sources. The number of PCA components was again from 0 to 20. Figure 14 shows that the filter scale has little effect on the mean absolute residual, but that it is reduced by increasing the number of PCA components. We decided to use a filter scale of 320′′ with 14 PCA components; there was little improvement by increasing the number of PCA components further and there was a marginal sign that using a filter with a smaller angular scale increased the mean absolute residual.

As before, we tested the effect of varying the 500µm threshold used to make the mask and of varying the tolerance value, both of which are used in the SCUBA-2 pipeline. We found that the mean absolute residual in the difference map varied very little when either parameter was adjusted. We therefore decided to use the same values as at 850µm.

We tested the effect of varying the feather scale, finding that the optimum feather scale was 40 arcsec, similar to the size of the Herschel beam at 500µm. We found very little difference in the resulting image when using feathering scales up to 100 arcsec (above 50 arcsec the low-resolution data must be weighted in the feathering, see Section 4.3).

The final stage in the simulations was to test the fidelity of the image made with the values of the parameters above. We used exactly the same procedure as at 850µm (Section 5.7). We found that at 450µm the noise estimate from the pipeline (σ\_pipe) was a much better estimate of the true noise (σ\_tot) than at 850µm. We found that the noise scaling term, b in Equation 1, was only 1.02, and the other two terms (a and f) were both zero. The input and the output images and the residual map divided by the noise value from the pipeline are shown in Figure 15. The fact that the residual map shows no structure at all demonstrates that at 450µm the random errors are much greater than the systematic errors.

It is known that Herschel can miss emission on the very largest scales, predominantly due to the finite size of the images. Clark et al. (2021) have investigated this for the Local Group, and found in the case of M31 that very little extended dust emission is missing from the SPIRE 500µm image. We therefore have chosen to feather with the normal SPIRE map, but have provided all the tools and instructions on our website if users wish to feather with an alternative map.

7. THE REAL DATA

7.1. Calibration

The SCUBA-2 MAKEMAP routine produces maps in instrumental units of picowatts, and so a flux conversion factor (FCF) is used to convert these units into either Jy beam\(^{-1}\) or Jy arcsec\(^{-2}\). There have recently been two changes at the JCMT, which have adjusted the standard FCF values used at the observatory. First, in November 2016 a filter set in SCUBA-2 was changed, which predominantly affected the 850µm FCF. Second, in May 2018 the maintenance of the secondary mirror resulted in a change in the value of the FCF for 450µm. We have observations both before and after these changes. Based on an interim analysis by observatory staff (private communication), we assume FCF values of 3.62 and 2.14 Jy pW\(^{-1}\) arcsec\(^{-2}\) at 450 and 850µm, respectively, for observations post May 2018. For our older observations, we multiply the ‘cleaned’ data (see Section 4.1) by a correction factor, so that the final data can be calibrated with the same FCF. We adopted values for this

---

Figure 15. As for Figure 11, but for the 450µm simulations.
correction factor of 1.21053 and 1.06481, for 450 and 850 µm, respectively.

The final factor we have to consider is that the standard JCMT calibration scheme is not designed for such extended objects as Andromeda. The JCMT calibration scheme (Dempsey et al. 2013) uses the flux of a calibrator source within a 30′′ radius aperture, after subtracting a background measured in an annulus around the calibrator between radii of 45 and 60 arcsec. This scheme is fine for calibrating images that contain point sources. But we are trying to calibrate very extended emission, and the beam of the telescope extends to much larger radii than the radii used in the standard calibration scheme.

We have adopted the calibration scheme we devised for the JINGLE Large Program (Smith et al. 2019), where we multiplied the FCFs so that the flux densities in the images matched the convention of other telescopes, that an aperture centered on a galaxy would only include the entire flux of the galaxy if the radius were increased to infinity. By integrating the beam model in Dempsey et al. (2013), we calculated that the standard 850µm FCF should be multiplied by 0.91, which agreed with the curve of growth found by Dempsey et al. (2013). Doing the same calculation at 450µm, we obtain a correction factor of 0.97. The curve of growth given in Dempsey et al. (2013), however, suggests a slightly smaller factor of 0.97. We suspect the difference is caused by extra non-Gaussian features in the beam at large radii. We therefore adopt the smaller value of 0.97. The final values of the FCF used to create these HASHTAG images were therefore the FCF values given above multiplied by these correction factors. These are 3.51 and 1.95 Jy pW⁻¹ arcsec⁻² at 450 and 850 µm, respectively.

7.2. Final Maps

The real HASHTAG data were reduced using the method outlined in the previous subsections, using the best values of the parameters found from the simulations. Our final maps (Data Release 1, DR1) are composed of two multi-extension fits files that contain the flux-density, uncertainty, and sensitivity maps for the 450 and 850µm images, respectively.

The uncertainty map contains the true uncertainty values we derived in Section 5.7, which includes both the statistical uncertainty in each pixel and the systematic uncertainty as the result of the flux density in that pixel (the third term in Equation 1). The sensitivity map is the same except that this map does not include the systematic term (f in Equation 1 is set to zero). At both wavelengths, the sensitivity of our final images exceeds our targets. In the 10 kpc ring, the typical sensitivity is ~2.0 and ~30 mJy beam⁻¹ at 850 and 450 µm, respectively, with peak sensitivities in the center of 1.5 and 20.6 mJy beam⁻¹ at 850 and 450 µm, respectively. As a rough comparison the Herschel 500µm observations have an instrumental sensitivity of ~11 mJy beam⁻¹ (Smith et al. 2017), and the point source sensitivity of Planck at 850 µm is ~69 mJy beam⁻¹ (Planck Collaboration et al. 2014c).

The flux-density and sensitivity maps are shown in Figure 16. The sensitivity is not quite as uniform at 450 µm, which we attribute to variations in sub-mm opacity during the periods we took the data, since opacity variations have a bigger effect at the shorter wavelength.

As well as the images shown in Figure 16, we also provide versions that have three different levels of Gaussian smoothing (for example, Figure 1), so that users can balance resolution versus signal-to-noise ratio. In these smoother images, the raw images have been smoothed with a Gaussian with a FWHM of 4, 5 and 7.9′′ at 450 µm and 7, 10 and 13′′ at 850 µm (this equates to effective resolutions of 8.9, 9.3, and 11.2′′ at 450 µm, and 15.2, 16.8, and 19.1′′ at 850 µm).

8. CO(J=3–2) SUBTRACTION

A possible contamination in the 850 µm image is the contribution of the CO(J=3–2) line, which has a rest frequency of 345.796 GHz, putting it within the 850 µm passband. This line has been shown to contribute anything from 0.7% to 41% of the 850 µm emission in nearby galaxies, although it is normally less than 15% (Smith et al. 2019), and in the Milky Way the contamination is typically small (<5%) but can be 30% (Moore et al. 2015). The contamination seems likely to be low in M31 because of the low fraction of molecular gas. We can get a rough idea of the likely scale of the contamination using our CO(J=3–2) survey of selected regions within the galaxy (Li et al. 2020). In our CO survey the strongest line flux we found was $I_{CO(J=3–2)} \approx 5 \, K \, km \, s^{-1}$, which corresponds, using the relationship given in Parsons et al. (2018), to an 850 µm flux density of ~3 mJy beam⁻¹, ~1.5 times the typical noise (Section 7.2).

We used the results of our CO(J=3–2) survey, which covered small regions but over a range of environments (Figure 2), as the ground truth for developing a method to estimate the CO contamination at all points across M31. As our starting point, we used the CO(J=3–2) cubes presented by Li et al. (2020). However, we created a new set of integrated intensity maps (moment-0 maps), using a new VLA Hα dataset (Koch et al. 2021). The VLA dataset provides a 58″ resolution (FWHM)
Figure 16. Our final 450 and 850 µm images and sensitivity maps for HASHTAG Data Release 1. The colored regions of the images are approximately where our observations and complete at our full sensitivity (equivalently, the grayscale shows regions where observations are still ongoing). The images have a resolution of 7.9" and 13.0" (FWHM), at 450 and 850 µm, respectively, and are available in both mJy beam$^{-1}$ and mJy arcsec$^{-2}$ units. The sensitivity maps are shown on a log scale and are described in Section 7.2.
image of the entire galaxy, and a higher resolution 18″ image of the region covered by Hubble. To create the CO integrated intensity maps we use the HI data as a prior to mask the channels in the cube that are not expected to contain any CO emission, using the moment-1 map to predict the center of the line with a width based on the HI line-width (with a minimum 40 km s\(^{-1}\) adopted). Using the HI as a prior is a similar technique to that applied by Schruba et al. (2011).

Our overall approach was to use a combination of several datasets to predict the CO\((J=3\rightarrow 2)\) emission, using our own CO\((J=3\rightarrow 2)\) survey to determine the combination that gives the best prediction. We included maps of the dust emission (column-density, temperature, and emissivity index; Whitworth et al. 2019), images in the Wide-field Infrared Survey Explorer (WISE) bands (Wright et al. 2010; Cutri et al. 2013), in the UV (Thilker et al. 2005), in the mid-infrared (Spitzer, MIPS; Gordon et al. 2006), a survey of part of the galaxy with CARMA in CO\((J=1\rightarrow 0)\) (Calduti-Primo & Schruba 2016, A. Schruba et al., in preparation), and a map of the estimated star-formation rate in the galaxy calculated using UV and 24μm (Ford et al. 2013). While some of these datasets may be degenerate, our aim was to find the best model to predict the CO\((J=3\rightarrow 2)\) line flux, rather than understanding the physical meaning of the model obtained.

The most useful dataset for predicting the CO\((J=3\rightarrow 2)\) emission is a map in another CO line. We decided not to use the map in the CO\((J=1\rightarrow 0)\) line over the whole galaxy (Nieten et al. 2006) because its resolution (23″) is significantly lower than that of our 850μm image (13″), and we found that a model derived at 23″ resolution when applied on 13″ scales did not perform as well as one derived at the higher resolution. The CARMA survey was our key dataset because it was a survey in the CO\((J=1\rightarrow 0)\) line with a resolution of 5.5″ (we use the version corrected for missing large-scale CO emission using the IRAM single-dish data). The survey, however, only covers ~323 arcmin\(^2\) (see Figure 19) and our CO\((J=3\rightarrow 2)\) survey covers an even smaller region (see Figure 2). We were therefore forced to develop a two-stage method.

In the first stage of the approach, we restricted our analysis to the small portion of the galaxy covered by our CO\((J=3\rightarrow 2)\) survey that was also within the region covered by CARMA. We do not explicitly include the CO\((J=3\rightarrow 2)/\text{CO}(J=1\rightarrow 0)\) ratio, which has been found to vary across M 31 (Li et al. 2020), but implicitly include it in the model. We first performed a background subtraction on the input continuum images where necessary, convolved these images to the same resolution as the 850μm/JCMT CO products, and finally re-projected them to match each of the six JCMT CO\((J=3\rightarrow 2)\) integrated intensity maps that overlap with the CARMA field. We took as our inputs the logarithms of all the input maps except for the dust temperature and emissivity index. We assigned the pixels randomly into a two-stage method.

The most useful dataset for predicting the CO\((J=3\rightarrow 2)\) emission is a map in another CO line. We decided not to use the map in the CO\((J=1\rightarrow 0)\) line over the whole galaxy (Nieten et al. 2006) because its resolution (23″) is significantly lower than that of our 850μm image (13″), and we found that a model derived at 23″ resolution when applied on 13″ scales did not perform as well as one derived at the higher resolution. The CARMA survey was our key dataset because it was a survey in the CO\((J=1\rightarrow 0)\) line with a resolution of 5.5″ (we use the version corrected for missing large-scale CO emission using the IRAM single-dish data). The survey, however, only covers ~323 arcmin\(^2\) (see Figure 19) and our CO\((J=3\rightarrow 2)\) survey covers an even smaller region (see Figure 2). We were therefore forced to develop a two-stage method.

In the first stage of the approach, we restricted our analysis to the small portion of the galaxy covered by our CO\((J=3\rightarrow 2)\) survey that was also within the region covered by CARMA. We do not explicitly include the CO\((J=3\rightarrow 2)/\text{CO}(J=1\rightarrow 0)\) ratio, which has been found to vary across M 31 (Li et al. 2020), but implicitly include it in the model. We first performed a background subtraction on the input continuum images where necessary, convolved these images to the same resolution as the

Note—The best-fit parameters from the model described by Equation 2, for both the model including CARMA observations (‘stage 1’) and that excluding CARMA observations (‘stage 2’). See Section 8 for more details.
average accuracy is \( \sim 28\% \), although the true uncertainty may be lower because there is significant uncertainty associated with some of the data points.

In the second stage of our method, we extend our analysis to create a model for regions of M31 where we do not have CARMA CO\((J=1-0)\) observations. To create this model we extend our analysis to the entire CARMA region, for which we have CO\((J=1-0)\) observations but not CO\((J=3-2)\) observations. In this much larger region we use the linear combination we derived in stage 1 to predict the CO\((J=3-2)\) fluxes. We then use these predictions as the ‘measurements’ in this stage of the analysis, as well as our JCMT CO\((J=3-2)\) measurements not used in ‘stage 1’ (e.g., outside the CARMA footprint). In this stage we use equation 2 as above to determine the combination of inputs that makes the best prediction of the CO\((J=3-2)\) ‘measurements’, except this time we do not use the CARMA CO\((J=1-0)\) measurements as one of the inputs.

We found, as before, that there was no advantage when using the non-linear methods, so we used the simpler linear method. CARMA covers a large continuous region, so instead of assigning pixels randomly to the training and test data, we used slices in declination, which avoids pixels in the same cloud being assigned to both datasets. Since predicted CO\((J=3-2)\) fluxes below 0.5K km s\(^{-1}\) correspond to 850\(\mu\)m fluxes significantly less than the statistical noise in the HASHTAG image, we only trained our model on regions with CO\((J=3-2)\) ‘measurements’ greater than this value. Figure 18 shows the relationship between the prediction of this new model versus the CO\((J=3-2)\) measurements (either our real measurements or the predictions from stage 1).

Figure 19 shows the CO\((J=3-2)\) line flux predicted by our models. Inside the CARMA region, where we have CO\((J=1-0)\) measurements, we have used the stage 1 model. Outside the CARMA region, we used our stage 2 model. The statistical noise in the HASHTAG 850\(\mu\)m image is \( \sim 2 \) mJy, which corresponds to a CO\((J=3-2)\) line flux of \( \sim 3 \) K km s\(^{-1}\). The figure shows that generally the line contamination is not a problem. In bright cores, though, it can be important. If \( \sigma_{850\mu m} \) is the statistical uncertainty in the 850\(\mu\)m without the inclusion of the systematic term (the third term in equation 1), the maximum CO\((J=3-2)\) signal is \( \sim 5.7\sigma_{850\mu m} \). But if the systematic term is included, this reduces to \( \sim 1.5\sigma \). If only pixels are included where the signal-to-noise ratio of the 850\(\mu\)m image is greater than 3 \( \sigma \) (not including the systematic term), the maximum contamination in a pixel is 28\%, but in 80\% of the pixels the CO line flux is less than 0.5 K km s\(^{-1}\), which is only \( \sim 16\% \) of the statistical noise in the continuum map. In general, then, contamination by the CO\((J=3-2)\) line is not a significant problem. We have provided 850\(\mu\)m images in the...
9. CONCLUSIONS

We have presented submillimeter images of the Andromeda galaxy obtained at 450 and 850 µm, the first images made from the ground that properly represent the structure of the galaxy on all spatial scales. We have described the method we have developed to optimize the SCUBA-2 pipeline for M31 and how we use a feathering technique to combine the small-scale structure (high-k Fourier components) from SCUBA-2 and data from space observatories (Herschel and Planck) to provide the large-scale structure (low-k Fourier components).

We describe the maps that comprise the HASHTAG DR1 data release, which have a typical sensitivity of \( \sim 2.0 \) and \( \sim 30 \) mJy beam\(^{-1} \) at 850 and 450 µm, respectively (at native SCUBA-2 resolution). As the CO\((J=3-2)\) line falls within the bandpass of the 850 µm band we derive a method to predict the line flux across M31, and find that while generally the contamination is small compared with the uncertainty in our continuum measurement, for some bright regions of the ring the contamination is significant. We provide data products both with and without the CO correction and at different resolutions.
