ABSTRACT

The surface-density profiles (SDPs) of dense filaments, in particular those traced by dust emission, appear to be well fit with Plummer profiles, i.e. $\Sigma(b) = \Sigma_B + \Sigma_O\{1 + [b/w_O]^2\}^{[1-p]/2}$. Here, Σ_B is the background surface density; $\Sigma_B + \Sigma_O$ is the surface density on the filament spine; b is the impact parameter of the line-of-sight relative to the filament spine; w_O is the Plummer scale-length (which for fixed p is exactly proportional to the full width at half-maximum, $w_O = \text{FWHM}/2\{2^{2/[p-1]} - 1\}^{1/2}$); and p is the Plummer exponent (which reflects the slope of the SDP away from the spine). In order to improve signal to noise, it is standard practice to average the observed surface densities along a section of the filament, or even along its whole length, before fitting the profile. We show that, if filaments do indeed have intrinsic Plummer profiles with exponent $p_{\text{INTRINSIC}}$, but there is a range of w_O values along the length of the filament (and secondarily a range of Σ_B values), the value of the Plummer exponent, p_{FIT}, estimated by fitting the averaged profile, may be significantly less than $p_{\text{INTRINSIC}}$. The decrease, $\Delta p = p_{\text{INTRINSIC}} - p_{\text{FIT}}$, increases monotonically (i) with increasing $p_{\text{INTRINSIC}}$; (ii) with increasing range of w_O values; and (iii) if (but only if) there is a finite range of w_O values, with increasing range of Σ_B values. For typical filament parameters, the decrease is insignificant if $p_{\text{INTRINSIC}} = 2$ ($0.05 \lesssim \Delta p \lesssim 0.10$), but for $p_{\text{INTRINSIC}} = 3$, it is larger ($0.18 \lesssim \Delta p \lesssim 0.50$), and for $p_{\text{INTRINSIC}} = 4$, it is substantial ($0.50 \lesssim \Delta p \lesssim 1.15$). On its own, this effect is probably insufficient to support a value of $p_{\text{INTRINSIC}}$ much greater than $p_{\text{FIT}} \simeq 2$, but it could be important in combination with other effects.

Key words: stars: formation – ISM: clouds.

1 INTRODUCTION

In the last decade, it has become clear that filaments play a critical role in assembling the material to form stars (e.g. Schneider & Elmegreen 1979; Bally et al. 1987; Abergel et al. 1994; Cambrésy 1999; Myers 2009; Hacar & Tafalla 2011; Peretto et al. 2012; Hacar et al. 2013; Palmeirim et al. 2013; Peretto et al. 2013; Alves de Oliveira et al. 2014; André et al. 2014; Könyves et al. 2015; Marsh et al. 2016; Hacar, Tafalla & Alves 2017; Ward-Thompson et al. 2017; Hacar et al. 2018; Williams et al. 2018; Watkins et al. 2019; Ladjelate et al. 2020; Arzoumanian et al. 2021). Even in clouds that are not apparently forming stars, or forming them very slowly (e.g. Joncas, Boulanger & Dewdney 1992; Falgarone, Pety & Phillips 2001; McClure-Griffiths et al. 2006; Ward-Thompson et al. 2010), including The Brick in the Central Molecular Zone of the Galaxy (Federrath et al. 2016), the internal structure is still dominated by filaments.

Filaments are particularly pronounced in maps of thermal dust-emission, such as those made using the Herschel Space Telescope (e.g. André et al. 2010; Men'shchikov et al. 2010; Molinari et al. 2010; Hill et al. 2011; Hennemann et al. 2012; Schneider et al. 2012; Schisano et al. 2014; Benedettini et al. 2015; Wang et al. 2015; Cox et al. 2016). Given maps of thermal dust emission at a range

of different wavelengths, it is possible to derive maps of the dust optical depth, τ_F at a fiducial far-infrared wavelength, λ_F, either by Modified Blackbody fitting (e.g. Hill et al. 2011; Peretto et al. 2012; Schneider et al. 2012; Palmeirim et al. 2013; Alves de Oliveira et al. 2014; Benedettini et al. 2015; Wang et al. 2015; Cox et al. 2016; Ladjelate et al. 2020), or by more sophisticated techniques (e.g. Howard et al. 2019, 2021) like PPMAP (Marsh, Whitworth & Lomax 2015; Whitworth et al. 2019). Such maps are more accurate if the range of wavelengths (a) is large, and (b) extends well above and well below the peak of the spectral energy distribution. It is also necessary that the emission at all the wavelengths used be optically thin.

If the mass opacity, κ_F, of dust at λ_F is known (and universal), one can convert a map of τ_F into a map of the surface density of dust, $\Sigma_D = \tau_F/\kappa_F$. If the fraction of dust by mass, Z_D is known (and universal), one can convert this map into a map of the total surface density (hereafter simply 'the surface density'), $\Sigma = \Sigma_D/Z_D$. Finally, if one assumes that all the hydrogen is molecular, one can convert the map of Σ into a map of the column-density of molecular hydrogen, $N_{H_2} = X\Sigma/2m_H$. Here, X is the fraction of hydrogen by mass and m_H is the mass of an hydrogen atom. With $X = 0.70$ this reduces to

$$N_{H_2} = 4.4 \times 10^{19} \, \text{cm}^{-2} \left[\frac{\Sigma}{M_\odot \, \text{pc}^{-2}} \right]. \quad (1)$$

However, this last conversion neglects the fact that on most lines of sight a significant fraction of the hydrogen is not molecular.

Therefore, in the sequel, we prefer to present our analysis in terms of Σ.

1.1 Plummer profiles

Dust-emission filaments are found to have surface-density profiles (hereafter SDPs) that can be fit with Plummer profiles,

$$\Sigma(b) = \Sigma_B + \Sigma_O \left\{ 1 + \left[\frac{b}{w_O} \right]^2 \right\}^{-[p-1]/2}, \tag{2}$$

(e.g. Arzoumanian et al. 2011; Palmeirim et al. 2013; Cox et al. 2016; André et al. 2016; Arzoumanian et al. 2019; Howard et al. 2019, 2021). In equation (2), Σ_B is the background surface density, $\Sigma_B + \Sigma_O$ is the surface density on the filament spine, b is the impact parameter of the line-of-sight relative to the filament spine (i.e. projected distance from the filament spine), w_O is the Plummer scale-length relating to the width of the densest part of the filament, and p is the Plummer exponent relating to the density gradient in the outer parts of the filament.

The full-widths at half-maximum surface density is related to w_O by

$$\text{FWHM} \simeq 2w_O \left\{ 2^{2/[p-1]} - 1 \right\}^{1/2}, \tag{3}$$

so for fixed p, the FWHM is exactly proportional to w_O. Implicitly the Plummer exponent is

$$p = 1 - \text{LIM}_{b \to \infty} \left\{ \frac{d \ln(\Sigma - \Sigma_B)}{d \ln(b)} \right\}. \tag{4}$$

Provided that (a) the contribution from the background (Σ_B) is uniform, and (b) the filament is cylindrically symmetric, the filament's underlying volume-density profile (VDP) should also subscribe to a Plummer profile, viz.

$$\rho(w) = \rho_B + \rho_O \left\{ 1 + \left[\frac{w}{w_O} \right]^2 \right\}^{-p/2}, \tag{5}$$

as shown by Casali (1986). Here, ρ_B is the background volume-density, ρ_O is the excess volume-density on the filament spine, w is the true (i.e. 3D) radial distance from the filament spine, and w_O is the same Plummer scale-length as invoked in equations (2) and (3). Implicitly the Plummer exponent is

$$p = -\text{LIM}_{w \to \infty} \left\{ \frac{d \ln(\rho - \rho_B)}{d \ln(w)} \right\}, \tag{6}$$

and

$$\rho_O = \frac{\Sigma_O \, \Gamma(p/2) \, \cos(\psi)}{w_O \, \Gamma(1/2) \, \Gamma(p/2 - 1/2)}; \tag{7}$$

Γ is the gamma function and ψ is the angle between the filament spine and the plane of the sky.

1.2 Longitudinally averaged filament profiles

When fitting SDPs with Plummer profiles (i.e. equation 2), it is a standard practice to first derive a single profile averaged along the length of the whole filament or a section thereof (in order to improve signal to noise), and then to estimate the Plummer parameters that best fit these longitudinally averaged filament profiles (e.g. Arzoumanian et al. 2011, 2019; Howard et al. 2019, 2021). We distinguish parameters derived in this way with a subscript 'FIT'.

$\Sigma_{B:\,FIT}$ and $\Sigma_{O:\,FIT}$ can be determined directly (modulo some straightforward interpolation). There are then only two further

Table 1. The box-car distribution parameters (hereafter simply 'the distribution parameters'). The left hand column gives the fixed values of μ_X, which represents the mean of $\log_{10}(X)$. The right hand column gives the range of σ_X that we explore, where σ_X represents the standard deviation of $\log_{10}(X)$. X stands for $[\Sigma_B/M_\odot \, pc^{-2}]$, $[\Sigma_O/M_\odot \, pc^{-2}]$ and $[w_O/pc]$.

FIXED MEANS	RANGES OF STANDARD DEVIATIONS
Background surface density, $[\Sigma_B/M_\odot \, pc^{-2}]$:	
$\mu_{\Sigma_B} = 1.778$	$0 \leq \sigma_{\Sigma_B} \leq 0.40$
Excess surface density on filament spine $[\Sigma_O/M_\odot \, pc^{-2}]$.	
$\mu_{\Sigma_O} = 1.778$	$0 \leq \sigma_{\Sigma_O} \leq 0.40$
Plummer scale-length of filament, $[w_O/pc]$.	
$\mu_{w_O} = -1.523$	$0 \leq \sigma_{w_O} \leq 0.40$

parameters to estimate: $w_{O:\,FIT}$ (or strictly speaking its angular equivalent, $\theta_{O:\,FIT} = w_{O:\,FIT}/D$, where D is the distance to the source); and p_{FIT}. Values of $w_{O:FIT} \sim 0.03$ pc (corresponding to FWHM ~ 0.1 pc) and $p_{FIT} \sim 2$ are commonly reported for the filaments observed in local molecular clouds (e.g. Arzoumanian et al. 2011; Palmeirim et al. 2013; André et al. 2014; Arzoumanian et al. 2019), and also for the filaments identified in hydrodynamic and magneto-hydrodynamic simulations of turbulent molecular clouds (e.g. Smith, Glover & Klessen 2014; Kirk et al. 2015; Federrath 2016; Priestley & Whitworth 2020).

However, Panopoulou et al. (2017) have pointed out that the distribution of intrinsic FWHM values for interstellar filaments, although centred on ~ 0.1 pc, may be significantly broader than reported, due to the averaging process.

Here, we show that the intrinsic p values of interstellar filaments (hereafter $p_{\text{INTRINSIC}}$) may also be larger than reported, i.e. $p_{\text{INTRINSIC}} > p_{FIT}$, again due to the averaging process. Specifically, the reduction, $\Delta p = p_{\text{INTRINSIC}} - p_{FIT}$ is larger for larger values of $p_{\text{INTRINSIC}}$. Δp is also larger if the range of w_O values is larger. And finally, provided there is a finite range of w_O values, Δp is larger if the range of Σ_B values is larger.

We define our computational methodology in Section 2. We present our results in Section 3. We summarise our conclusions in Section 4.

2 COMPUTATIONAL METHODOLOGY

2.1 Logarithmic box-car distributions

In the sequel, SDPs are generated with the Plummer exponent held fixed at $p = p_{\text{INTRINSIC}}$. For each of the other three parameters defining the Plummer SDP (i.e. $X \equiv [\Sigma_B/M_\odot \, pc^{-2}]$, $[\Sigma_O/M_\odot \, pc^{-2}]$, $[w_O/pc]$; see equations 2 and 3) we assume that $\log_{10}(X)$ has a box-car distribution, with mean μ_X and standard deviation σ_X,[1] i.e.

$$\frac{dP}{d\log_{10}(X)} = \begin{cases} \frac{d\log_{10}(X)}{2\sqrt{3}\,\sigma_X}, & |\log_{10}(X) - \mu_X| \leq \sqrt{3}\sigma_X; \\ 0, & |\log_{10}(X) - \mu_X| > \sqrt{3}\sigma_X. \end{cases} \tag{8}$$

2.2 Filament configurations

For the purpose of this study, all the means (μ_{Σ_B}, μ_{Σ_O}, μ_{w_O}) have fixed values, as given in the left hand column of Table 1. These correspond to a median background surface density, $\Sigma_B = 60 \, M_\odot \, pc^{-2}$ (equivalently $N_{H_2} \simeq 2.6 \times 10^{21} \, cm^{-2}$), a median spinal

---

[1] Strictly speaking, 'μ_X' should read '$\mu_{\log_{10}(X)}$', and 'σ_X' should read '$\sigma_{\log_{10}(X)}$'. We use the shorter version for convenience.

surface density $\Sigma_O = 60\,M_\odot\,pc^{-2}$, and a median Plummer scale-length $w_O = 0.03\,pc$. These choices of μ_{Σ_B}, μ_{Σ_O}, and μ_{w_O} are informed by the results of Arzoumanian et al. (2019).

The different filament configurations that we explore, are therefore, completely defined by specifying the three standard deviations: σ_{Σ_B}, σ_{Σ_O}, and σ_{w_O}. We consider values for these standard deviations within the limits specified in the right hand column of Table 1. A large standard deviation means that the associated parameter varies over a large range. The maximum standard deviations considered allow Σ_B and Σ_O to take values between 12 and $300\,M_\odot\,pc^{-2}$; and w_O to take values between 0.006 and 0.15 pc. We are not suggesting that such extreme values of Σ_B, Σ_O, and w_O are the norm. Large values are treated in order to evaluate trends accurately. We discuss in Appendix A (see Table A1), the standard deviations that are actually observed.

2.3 Multiple realisations and longitudinally averaged profiles

For each filament configuration (i.e. each specific combination of σ_{Σ_B}, σ_{Σ_O}, and σ_{w_O}), we generate $c_{TOT} = 10^6$ different random combinations of Σ_B, Σ_O, and w_O. For example, different values of Σ_O are obtained by generating linear random deviates, $\mathcal{L}$, on the interval [0,1], and then setting

$$\Sigma_O = 10^{\mu_{\Sigma_O} + \sqrt{3}\sigma_{\Sigma_O}[2\mathcal{L}-1]}. \tag{9}$$

Each combination of Σ_B, Σ_O, and w_O allows us to compute an individual SDP, and these individual SDPs are added and normalised to produce a longitudinally averaged SDP, $\Sigma_{FIT}(b)$, for that filament configuration. The results presented below involve $\sim 5 \times 10^5$ different filament configurations, and hence $\sim 5 \times 10^{11}$ individual SDPs.

2.4 Plummer profile fitting

The average SDP, $\overline{\Sigma}_{CONFIG}(b)$, for a given filament configuration, $[\sigma_{\Sigma_B}, \sigma_{\Sigma_O}, \sigma_{w_O}]$, is fit with a Plummer-profile (equation 2), and the best-fit parameters, ($\Sigma_{B:\,FIT}$, $\Sigma_{O:\,FIT}$, and $w_{O:\,FIT}$) are established to five significant figures. The quality of the fit is measured with the fractional root mean square error, $\mathcal{Q}_{FIT}$, given by

$$\mathcal{Q}_{FIT}^2 = \frac{1}{i_{TOT}} \sum_{i=1}^{i=i_{TOT}} \left\{ \frac{1}{\overline{\Sigma}_{CONFIG}^2(b_i)} \left[\overline{\Sigma}_{CONFIG}(b_i) - \Sigma_{B:FIT} \right.\right.$$
$$\left.\left. - \Sigma_{O:FIT} \left\{ 1 + \left[\frac{b_i}{w_{O:FIT}} \right]^2 \right\}^{-[p_{FIT}-1]/2} \right]^2 \right\}. \tag{10}$$

Here, the b_i ($i = 1$ to $i_{TOT} = 401$) are impact parameters uniformly spaced between $b_1 = 0.000\,pc$ and $b_{401} = 0.400\,pc$.

2.5 Correlated Plummer parameters

Arzoumanian et al. (2019) note that the surface density on the filament spine is correlated with the background surface density (see their fig. 6c and the associated caption). Specifically they find

$$N_{H_2:O} \simeq [0.95 \pm 0.15]N_{H_2:B} - [0.15 \pm 0.39] \times 10^{21}\,cm^{-3}, \tag{11}$$

where $N_{H_2:B} + N_{H_2:O}$ is the column-density of molecular hydrogen on the filament spine, and $N_{H_2:B}$ is the column-density of molecular hydrogen in the background. We have therefore, repeated our analysis with the equation for generating values of Σ_O (i.e. equation 9) replaced by the equivalent equation in terms of surface density:

$$\Sigma_O = \left\{ 0.95\,\Sigma_B - 3.4\,M_\odot\,pc^{-2} \right\} 10^{\sqrt{3}\sigma_{\Sigma_O}[2\mathcal{L}-1]}. \tag{12}$$

In Appendix A, we discuss the Arzoumanian et al. (2019) data set in more detail, and possible reasons for this correlation. We do not consider correlations between any of the other pairs of Plummer distribution parameters.

3 RESULTS

We are concerned here with the values of p_{FIT} for a longitudinally averaged SDP when there are significant variations in the background surface density, Σ_B, and/or the spinal surface density, Σ_O, and/or the radial scale-length, w_O, along the filament or section of filament being considered.

We label w_O the *primary* parameter, because a finite range of w_O values always produces a reduction in p_{FIT}, irrespective of whether there is variation in Σ_B or Σ_O. The reduction increases with increasing range (i.e. increasing σ_{w_O}).

We label Σ_B the *secondary* parameter, because a finite range of Σ_B values only produces a reduction in p_{FIT} when there is also a finite range of w_O values. The associated reduction is relatively small, and increases with both the range of w_O values and the range of Σ_B values (i.e. increasing σ_{w_O} and increasing σ_{Σ_B}). The reduction associated with the range of Σ_B values tends to saturate at large σ_{Σ_B}

We label Σ_O the *null* parameter, because whatever the range of Σ_O values it has no effect on p_{FIT}.

3.1 One parameter at a time

To demonstrate these dependences, we first consider one parameter at a time, and increase the range of that parameter while keeping the other two parameters fixed. In other words, we vary one of σ_{Σ_B}, σ_{Σ_O}, and σ_{w_O} in turn, and set the other two to zero.

If we increase σ_{Σ_B} (i.e. we increase the range of Σ_B), with $\sigma_{\Sigma_O} = \sigma_{w_O} = 0$ (i.e. fixed $\Sigma_O = 60\,M_\odot\,pc^{-2}$ and fixed $w_O = 0.03\,pc$), this has no effect on p_{FIT}, which remains exactly equal to $p_{INTRINSIC}$.

Likewise, if we increase σ_{Σ_O} (i.e. we increase the range of Σ_O), with $\sigma_{\Sigma_B} = \sigma_{w_O} = 0$ (i.e. fixed $\Sigma_B = 60\,M_\odot\,pc^{-2}$ and fixed $w_O = 0.03\,pc$), this too has no effect on p_{FIT}, which remains exactly equal to $p_{INTRINSIC}$.

However, if we increase σ_{w_O} (i.e. we increase the range of w_O), with $\sigma_{\Sigma_B} = \sigma_{\Sigma_O} = 0$ (i.e. fixed $\Sigma_B = 60\,M_\odot\,pc^{-2}$ and fixed $\Sigma_O = 60\,M_\odot\,pc^{-2}$), p_{FIT} is reduced, as shown on Fig. 1. w_O is therefore, the primary parameter on the grounds that it is the only parameter whose variation, on its own, affects p_{FIT}. Moreover, it affects p_{FIT} strongly if $p_{INTRINSIC}$ is large.

3.2 Two parameters at a time

Next we consider two parameters at a time, and vary the ranges of those two parameters simultaneously while keeping the value of the third parameter fixed at its default value. In other words, we vary two of σ_{Σ_B}, σ_{Σ_O}, and σ_{w_O}, and set the remaining one to zero.

If we vary the range of Σ_B (i.e. vary σ_{Σ_B}) and simultaneously vary the range of Σ_O (i.e. vary σ_{Σ_O}), with w_O fixed at its default value (i.e. $w_O = 0.03\,pc$), the value of p_{FIT} is unaffected, and remains at $p_{INTRINSIC}$.

If we vary the range of Σ_B (i.e. vary σ_{Σ_B}) and simultaneously vary the range of w_O (i.e. vary σ_{w_O}), with Σ_O fixed at its default value (i.e. $\Sigma_O = 60\,M_\odot\,pc^{-2}$), both variations produce a change in p_{FIT}. Fig. 2 shows contours of constant p_{FIT} on the (σ_{w_O}, σ_{Σ_B}) plane, for filaments with $p_{INTRINSIC} = 4$; similarly Figs 3 and 4 show the analogous results for $p_{INTRINSIC} = 3$ and $p_{INTRINSIC} = 2$, respectively. In each case, we see that w_O is the primary parameter; at fixed σ_{Σ_B},
Figure 1. The variation of p_{FIT} with σ_{w_O} when the other ranges are set to zero ($\sigma_{\Sigma_B} = \sigma_{\Sigma_O} = 0$). Results are shown for $p_{INTRINSIC} = 4.0, 3.5, 3.0, 2.5,$ and 2.0, as labelled. For each curve, 401 profiles have been generated and fitted. For the $p_{INTRINSIC} = 4.0, 3.5, 3.0, 2.5,$ and 2.0 curves the average fractional root-mean-square error is $\bar{\mathcal{Q}} = 0.012(\pm 0.011)$, $0.012(\pm 0.010)$, $0.010(\pm 0.008)$, $0.008(\pm 0.005)$, and $0.006(\pm 0.004)$, respectively (see equation 10).
Figure 2. Contours of constant p_{FIT} on the $[\sigma_{w_O}, \sigma_{\Sigma_B}]$ plane for $p_{INTRINSIC} = 4$. The 1.6×10^5 profiles generated and fitted for this plot have an average fractional root mean square error $\bar{\mathcal{Q}} = 0.0012(\pm 0.0034)$ (see equation 10). The numbers in square brackets represent the values for filaments in different regions: [0] All regions; [1] IC5146; [2] Orion B; [3] Aquila; [4] Musca; [5] Polaris; [6] Pipe; [7] Taurus L1495; [8] Ophiuchus (see Appendix A for details).

p_{FIT} decreases monotonically and relatively rapidly with increasing σ_{w_O}, especially for larger $p_{INTRINSIC}$. Σ_B is the secondary parameter: At fixed but finite σ_{w_O}, p_{FIT} decreases monotonically but relatively slowly with increasing σ_{Σ_B}, and tends towards a constant asymptotic value.

Finally, if we vary the range of Σ_O (i.e. vary σ_{Σ_O}) and simultaneously vary the range of w_O (i.e. vary σ_{w_O}), with Σ_B fixed at it default value (i.e. $\Sigma_B = 60 \, M_{\odot} \, pc^{-2}$), we find that p_{FIT} is completely independent of the value of σ_{Σ_O}, and depends on σ_{w_O} in exactly the same way as when σ_{w_O} was varied on its own, i.e. as shown on Fig. 1. Thus, Σ_O is a null parameter: Under no circumstance does its range have an effect on p_{FIT}.

**Figure 3.** As Fig. 2, but for $p_{INTRINSIC} = 3$; $\bar{\mathcal{Q}} = 0.0011(\pm 0.0028)$.

Figure 4. As Fig. 2, but for $p_{INTRINSIC} = 2$; $\bar{\mathcal{Q}} = 0.0006(\pm 0.0016)$.

3.3 Effect of correlation between Σ_O and Σ_B

If we include the correlation between Σ_O and Σ_B (i.e. we generate values of Σ_O using equation 12 rather than equation 9), the results are unchanged. This is unsurprising, since Σ_O is the null parameter.

3.4 Comparison with observational data

The numbers in square brackets on Figs 2, 3, and 4 show the values of σ_{w_O} and σ_{Σ_B} estimated for the different regions analysed by Arzoumanian et al. (2019), as per the key in the caption to Fig. 2 and Table A1 in Appendix A.

As treated here, the effect we have evaluated appears insufficient to reduce $p_{INTRINSIC}$ from $p_{INTRINSIC} = 4.0$ (as appropriate for an isolated, infinitely ong, isothermal filament in hydrostatic equilibrium, Ostriker 1964) to $p_{FIT} \sim 2$ (as reported by e.g. Arzoumanian et al. 2011; Palmeirim et al. 2013; André et al. 2014; Federrath et al. 2016; Arzoumanian et al. 2019). However, we should note that Howard et al. (2019) find – on the basis of high-resolution maps derived using PPMAP – that they can obtain a better fit to small local sections of the L1495 filament in Taurus with $p_{FIT} = 4$ rather than $p_{FIT} = 2$.

A more accurate evaluation should take into account two factors. First, the averaging applied by Arzoumanian et al. (2019) only involves the profiles for individual filaments, and the range of w_O values for an individual filament is likely to be lower than the range

for the ensemble of all the filaments in a particular region. Correcting for this will decrease Δp. Second, the averaging over the ensemble of filaments will reduce the range of w_O values, as shown by Panopoulou et al. (2017), and correcting for this will increase Δp. Δp will always be positive, so p_{FIT} will always be less than $p_{INTRINSIC}$.

4 CONCLUSIONS

We have shown that averaging filament profiles can reduce the fitted Plummer exponent, p_{FIT} below its intrinsic value, $p_{INTRINSIC}$, i.e. it artificially reduces the slope of the SDS at large distance from the spine. (It is tempting to speculate that this effect operates even if the intrinsic SDP is not well fit by a Plummer profile, but we have not proven this.)

The amount of reduction is largely determined by the intrinsic Plummer exponent, $p_{INTRINSIC}$, and the range of Plummer scale lengths, w_O, with a small additional contribution from the range of background surface densities, Σ_B.

This reduction is not affected by the apparent correlation between the the spinal surface density, Σ_O and the background surface density, Σ_B, as reported in Arzoumanian et al. (2019). In Appendix A, we explore the causes of this correlation, and suggest that it may be largely a selection effect.

For the ranges reported by Arzoumanian et al. (2019), the effect we have evaluated cannot, on its own, support values of $p_{INTRINSIC}$ significantly greater than $p_{FIT} = 2$. Specifically, it appears that $p_{INTRINSIC} \simeq 4.0$ is only reduced to $p_{FIT} \gtrsim 3.0$ (see numbers in square brackets on Fig. 2), and $p_{INTRINSIC} \simeq 3.0$ is only reduced to $p_{FIT} \gtrsim 2.5$ (numbers on Fig. 3).

However, if there were some other effect that operated in tandem with the one we have evaluated, then values of $p_{INTRINSIC}$ significantly greater than $p_{FIT} \simeq 2$ might be plausible.

DATA AVAILABILITY

The provenance of the data used in this paper is described in Arzoumanian et al. (2019). All software used will be supplied on request to APW.

APPENDIX: THE ARZOUMANIAN ET AL. (2019) DATA-SET

Table A1 gives values of the distribution parameters derived from the large sample analysed by Arzoumanian et al. (2019), viz. $\mathcal{N}$ (the number of filaments analysed); μ_{FWHM}; and σ_{FWHM} (the mean and standard deviation for the logarithm of the full-width at half-maximum); μ_{Σ_B} and σ_{Σ_B} (the mean and standard deviation for the background surface density); and μ_{Σ_O} and σ_{Σ_O} (the mean and standard deviation for the spinal surface density). The values of σ are taken at their face value, although we note the arguments in Panopoulou et al. (2017) suggesting that they may be underestimates. (Since for a given $p_{INTRINSIC}$, the FWHM is proportional to w_O, we take the standard deviation of the logarithm of w_O to be the same as the standard deviation of the logarithm of FWHM.)

Fig. A1 shows the values of Σ_O and Σ_B for individual filaments. This is essentially the same as fig. 6c in Arzoumanian et al. (2019), except that the axes are Σ rather than N_{H_2} (see equation 1), and they are scaled equally. We have over-plotted (a) with a solid line the
Figure A1. The distribution of profile parameters on the $(\sigma_{\Sigma_B}, \sigma_{\Sigma_O})$ plane, and the corresponding moment ellipse (see the text for definition). The solid straight line shows the correlation determined by Arzoumanian et al. (2019), and the dashed line marks the contrast threshold used by Arzoumanian et al. (2019) to define a filament.

correlation derived by Arzoumanian et al. (2019),

$$\Sigma_O = 0.95\,\Sigma_B - 3.4\,M_\odot\,pc^{-2}, \tag{A1}$$

(b) with a dashed straight line the contrast threshold adopted by Arzoumanian et al. (2019),

$$C_O \equiv \Sigma_O/\Sigma_B > 0.3, \tag{A2}$$

and (c) with a solid line the 'moment ellipse'.

The moment ellipse is the ellipse which, if the same number of points were distributed uniformly within its boundary, would have the same centre of mass as the actual points, the same principal moments and the same principal axes. This is an alternative way of displaying a linear correlation between two variables (or their logarithms). It has the merit that it treats the two variables equivalently, i.e. it does not assume that one is dependent and the other independent.

Figure A2. Moment ellipses on the $(\sigma_{\Sigma_B}, \sigma_{\Sigma_O})$ plane for the different fields.

There are two key things to note about this plot. First, the column-density contrast threshold that Arzoumanian et al. (2019) apply, accounts for the lower cut-off in values of Σ_O, and is probably responsible for a significant part of the observed correlation. Second, the empty bit of the ellipse below this threshold is to some extent compensated by a concentration of points immediately above the threshold.

Fig. A2 shows the moment ellipses for the individual fields. It shows that within individual fields, the correlation between Σ_O and Σ_B varies. First, it is always steeper than for the ensemble of all the fields. In general, the spread of Σ_O values is larger than the spread of Σ_B values. Second, the cases where this is less marked are those more affected by the contrast threshold. Third, the extent of the correlation noted by Arzoumanian et al. (2019) can be attributed to systematic changes from one field to another, with Polaris at one extreme, Aquila at the other extreme, and Musca and Pipe in the middle (and having very little overlap with either Polaris or Aquila).

Table A1. Column 1 gives the name of the field considered, preceded by the number (in square brackets) used to represent this field on Figs 2, 3, and 4. Column 2 gives the number of filaments. Columns 3 and 4 give the mean, $\mu_{\rm FWHM}$, and standard deviation, $\sigma_{\rm FWHM}$, of $\log_{10}({\rm FWHM/pc})$, where FWHM is the full-width at half-maximum. Columns 5 and 6 give the mean, $\mu_{\Sigma_{\rm B}}$, and standard deviation, $\sigma_{\Sigma_{\rm B}}$, of $\log_{10}(\Sigma_{\rm B}/{\rm M}_\odot {\rm pc}^{-2})$, where $\Sigma_{\rm B}$ is the background surface density. Columns 7 and 8 give the mean, $\mu_{\Sigma_{\rm O}}$, and standard deviation, $\sigma_{\Sigma_{\rm O}}$, of $\log_{10}(\Sigma_{\rm O}/{\rm M}_\odot {\rm pc}^{-2})$, where $\Sigma_{\rm O}$ is the spinal surface density. Columns 9 through 11 refer to the moments of the distribution of profile parameters on the $(\sigma_{\Sigma_{\rm B}}, \sigma_{\Sigma_{\rm O}})$ plane: Column 9 gives the slope of the principal axis, columns 10 and 11 give, respectively, the major and minor axes of the moment ellipse.

FIELD	$\mathcal{N}$	$\mu_{\rm FWHM}$	$\sigma_{\rm FWHM}$	$\mu_{\Sigma_{\rm B}}$	$\sigma_{\Sigma_{\rm B}}$	$\mu_{\Sigma_{\rm O}}$	$\sigma_{\Sigma_{\rm O}}$	S	a	b
