1 **Abstract**

2 *Background.* Amyotrophic lateral sclerosis (ALS) is characterized by degeneration of motor
3 neurons resulting in muscle atrophy. In contrast to the lower motor neurons, the role of upper
4 (cortical) neurons in ALS is yet unclear. Maturation of locomotor networks is supported by
5 dopaminergic (DA) projections from substantia nigra to the spinal cord and striatum.

6 *Objective.* To examine the contribution of DA mediation in the striatum-cortex networks in
7 ALS progression. *Methods.* We studied electroencephalogram (EEG) from striatal putamen
8 (Pt) and primary motor cortex (M1) in Δ FUS(1-359)-transgenic (Tg) mice, a model of ALS.

9 EEG from M1 and Pt were recorded in freely moving young (two-month old) and older (five-
10 month old) Tg and non-transgenic (nTg) mice. EEG spectra were analyzed for 30 min before
11 and for 60 min after systemic injection of a DA mimetic, apomorphine (APO), and saline.

12 *Results.* In young Tg vs. nTg mice, baseline EEG spectra in M1 were comparable, whereas
13 in Pt, beta activity in Tg mice was enhanced. In older Tg vs. nTg mice, beta dominated in
14 EEG from both M1 and Pt, whereas *theta* and *delta 2* activities were reduced. In younger Tg
15 vs. nTg mice, APO increased *theta* and decreased *beta 2* predominantly in M1. In older
16 mice, APO effects in these frequency bands were inversed and accompanied by enhanced
17 *delta 2* and attenuated *alpha* in Tg vs. nTg mice. *Conclusion.* We suggest that revealed EEG
18 modifications in Δ FUS(1-359)-transgenic mice are associated with early alterations in the
19 striatum-cortex interrelations and DA transmission followed by adaptive intracerebral
20 transformations.

1 **1. Introduction**

2 Amyotrophic lateral sclerosis (ALS) is characterized by progressive degeneration of motor
3 neurons in the cortex and spinal cord that results in relentless muscle weakness. Various
4 transgenic ALS models on mice allow the analyses of different mechanisms underlying this
5 neurodegenerative pathology development (see for review, [1]). Within genetic mutations,
6 leading to ALS, the fused in sarcoma (*FUS*) proteinopathy has been shown to affect motor
7 neurons at both the upper and lower levels. While the lower motor neuron malfunctioning is
8 observed at many stages of ALS development (see for review, [2]), the upper cortical
9 neurons have been shown to precede this descending pathology [3]; these are considered as
10 one of the most challenging neuron populations to study [4]. In addition, modifications of
11 connections in cortical and subcortical neural networks are thought to be early pathogenic
12 events in ALS progression [5, 6]. In particular, corticostriatal synaptic plasticity changes
13 associated with degeneration of dopaminergic (DA) neurons in the substantia nigra (SN)
14 have been revealed in a transgenic mouse model of ALS [7]. However, little is known about
15 the role of the striatum-cortex interrelations in the developmental period in the subjects
16 disposed to ALS, despite the fact that locomotor network maturation has been shown to be
17 associated with ascending DA projections from SN to the striatum [8]. On the other hand,
18 aging, a major risk factor for neurodegenerative disorders, is thought to potentiate negative
19 effects of genetic aberrations thus promoting neurodegeneration in ALS, in particular [9]. ALS
20 cases with mutations in *FUS* have been revealed to have statistically earlier age of onset vs.
21 those in *SOD1* and *TARDBP* that allowed the hypotheses that in *FUS* model of ALS,
22 mechanisms perturbing the development, maintenance and homeostasis of the nervous
23 system in early postnatal life and in the aging process might be targeted (see for review,
24 [10]).

25 ALS model used in this study originates from ectopic expression of truncated *FUS*(1-359)
26 lacking nuclear localization signal under the control of pan-neuronal Thy-1 promoter that
27 leads to expression of transgenic human mutant *FUS* protein in mouse neuronal tissues.
28 One of the limitations of our model is inability to control the expression of pathogenic *FUS*
29 protein which results in constant accumulation of aberrant *FUS*(1-359) protein in neurons.
30 The build up leads to inevitable death of all motor neurons and subsequent paralysis typically
31 observed in humans. Yet, our model represents a powerful in vivo tool recapitulating key
32 molecular process of pathogenic protein aggregation progressing over animal's lifespan that
33 is long enough to capture any events preceding eventual protein aggregation. In these *FUS*-
34 transgenic and non-transgenic (control) mice at ages of two and five months, corresponding
35 to normal and critically low survival rates, respectively [11], we recorded EEG bilaterally from
36 the primary motor cortex (M1) and one of striatal nucleus, putamen (Pt), before and after
37 systemic injection of a non-selective DA agonist, apomorphine (APO). APO is a non-narcotic

1 morphine derivative that is well known to activate D2 subtype of DA receptors and, to a much
2 lesser extent, D1 receptors [12]. This allows the separation of so-called "indirect" and "direct"
3 cortico-striatal-cortical circuits, which are mediated via D2 and D1 receptors, respectively,
4 and differentially involved in movement regulation [13]. Furthermore, APO is thought to be a
5 promising neuroprotective agent against ALS [14]. Symmetrical EEG recordings from M1 and
6 Pt were assessed as impaired inter-hemispheric relations have been demonstrated in ALS
7 patients [15]. Significant differences between *FUS* and control mice were revealed in
8 frequency spectra of both baseline and APO-evoked EEG activities in the brain areas
9 studied.

11 2. Materials and Methods

12 Male transgenic (Tg) mice with truncated human *FUS* lacking nuclear localization signal
13 (*FUS* mice, $\Delta FUS(1-359)$), maintained on the CD-1 genetic background, and non-transgenic
14 littermates lacking mutant *FUS* transgene (nTg, wild type control) at ages of two and five
15 months were used in this study. The *FUS* mice were obtained from the Center for Collective
16 Use of the Institute of Physiologically Active Compounds RAS (Chernogolovka, Russian
17 Federation). Up to the ages of one and four months, the mice were housed in groups of five
18 per cage, while, thereafter, each of them was kept for 1.5 months in an individual cage. Mice
19 were housed in a standard environment (12-h light/dark cycle, 18-26°C room temperatures
20 and 30-70% relative humidity) with food and water ad libitum. The procedures were carried
21 out in accordance with the "Guidelines for accommodation and care of animals. Species-
22 specific provisions for laboratory rodents and rabbits" (GOST 33216-2014) and in compliance
23 with the principles enunciated in the Directive 2010/63/EU on the protection of animals used
24 for scientific purposes, and approved by the local Institute of Physiologically Active
25 Compounds Ethics Review Committee (protocol № 30, April 30, 2019). All mice were
26 genotyped using PCR analysis of DNA obtained from the ear/tail snips, followed by
27 separation of the reaction products in the agarose gel. Mice with a transgene cassette in the
28 genome were combined into Tg groups, whereas those with lacking transgene were placed
29 into nTg littermates' groups [11]. All efforts were made to minimize the number of the animals
30 and their suffering.

31 2.1. Electrodes implantation and EEG recording

32 After two weeks of adaptation to the individual cage, each of sixteen 2- and 5-month old
33 *FUS* mice (38.3 ± 2.5 g and 46.9 ± 2.5 g, respectively, N = 8 in each group) and fourteen nTg
34 mice (36.0 ± 1.3 g and 44.9 ± 2.2 g, respectively, N = 7 in each group) was anesthetized with
35 subcutaneous (s.c.) injection of a combination of dissolved tiletamine/zolazepam (Zoletil®,
36 Virbac, France) and xylazine solution (Rometar®, Bioveta, Czech Republic) at doses of 25
37 mg/kg and 2.5 mg/kg, respectively. Four recording electrodes were implanted bilaterally into

1 primary motor cortices (M1) and putamen (Pt) (AP: +1.1 mm anterior to bregma; ML: ± 1.5
2 mm lateral to midline; DV: -0.75 and -2.75 mm depths from skull surface, respectively) [16].
3 (Schematic electrodes positioning see in Suppl. 1). Custom made electrodes were
4 constructed from two varnish-insulated nichrom wires (100- μm diameter) glued together (3M
5 Vetbond™ Tissue Adhesive, MN, USA) with tips free from insulation for 70-100 μm and 2
6 mm apart from one another for simultaneous recording of EEG. These electrodes were
7 sufficiently inflexible, and had higher effective surface/volume ratio than a mono-wire
8 electrode of 200- μm diameter. The reference and ground electrodes (stainless steel wire, 0.4
9 mm in diameter) were placed symmetrically into the caudal cavities behind the cerebrum
10 (AP: -5.3, ML: ± 1.8 , DV: -0.5). All electrodes were positioned using a computerized 3D
11 stereotaxic StereoDrive (Neurostar, Germany), then fixed to the skull with dental cement and
12 soldered to a dual row male connector (Sullins Connector Solutions, CA, USA). After
13 electrode implantation, each animal was housed in an individual cage. Post-mortem
14 verification of the electrode tip location included several steps: an anodal current (80-100 μA ,
15 1 s) coagulation of the adjacent tissue, extirpation of the brain and fixation of the cerebrum in
16 4% paraformaldehyde. Using a freezing microtome (Reicher, Austria), the brain was cut in
17 30- μm sections that were examined to specify the electrode tip locations. Effective electrode
18 targeting of the chosen brain areas was based on the use of the stereotaxic manipulator and
19 precise measurement of the bregma and lambda coordinates. This high-tech manipulator
20 allows the drilling of the holes for the electrodes exactly in the selected points on the skull.
21 Precise estimations of an individual's bregma-lambda distance provide the correction of the
22 coordinates for the brain areas, taking into account that the value used for preparation of the
23 stereotaxic atlas [16] was equal to 4.2 ± 0.25 mm. The frozen slices with the most effective
24 electrode position were Nissl stained with cresyl violet acetate [17], magnified (Nikon Eclipse
25 E200 microscope, Japan) and digitized (DXM1200 camera, Japan) for further illustrations.

26 Three days after electrode implantation, each mouse was adapted for four days (1 h/day)
27 to an experimental cage (Perspex, 15x17x20 cm) located in an electrically shielded chamber
28 and to a cable (five 36-gauge wires, Plexon Inc, Texas, USA) plugged in a digital Neuro-MEP
29 amplifier (Neurosoft Ltd, Ivanovo, Russian Federation). On day 8, a baseline EEG was
30 recorded for 30 min, starting 20 min after placing the animal into the box. EEG recordings
31 were continued for 60 minutes after s.c. injection either saline (control) or, on the next day,
32 apomorphine (APO, Sigma, Milan, Italy), at a dose of 1.0 mg/kg. (For an overview of the
33 timeline and drug administration protocol, see Suppl. 2). To minimize the risk of oxidation
34 only freshly dissolved APO was used. All experiments were performed from 9 am to 6 pm in
35 daylight combined with an artificial light source keeping illumination at a relatively stable
36 level.

37 2.2. Computation of EEG frequency spectra

1 Monopolar EEG signals measured between the active and reference electrodes were
2 amplified, filtered (0.1-35 Hz) and sampled (1 kHz) on-line using the amplifier and kept in
3 memory of an operational computer for further analysis. The frequency spectra of successive
4 12-sec EEG epochs were studied using a modified version of period-amplitude analysis [18],
5 which, in contrary to the Fourier transform, was not affected by well-known non-stationary
6 nature of the EEG signals. The absolute values of the half-wave amplitudes with
7 periods/frequencies in each of selected narrow EEG frequency subbands were summed
8 followed by their normalization to the sum of all values calculated in the subbands. In this
9 study, twenty five subbands in the 0.48 - 31.5 Hz range were analyzed: 0.48 - 0.53 (0.5),
10 0.83 - 0.92 (0.9), 1.20 - 1.33 (1.3), 1.59 - 1.76 (1.7), 1.99 - 2.20 (2.1), 2.42 - 2.67 (2.5), 2.86 -
11 3.17 (3.0), 3.34 - 3.69 (3.5), 3.83 - 4.24 (4.0), 4.36 - 4.82 (4.6), 4.92 - 5.44 (5.2), 5.52 - 6.10
12 (5.8), 6.17 - 6.82 (6.5), 6.87 - 7.59 (7.2), 7.62 - 8.43 (8.0), 8.45 - 9.34 (8.9), 9.37 - 10.36
13 (9.9), 10.40 - 11.49 (10.9), 11.56 - 12.77 (12.2), 12.90 - 14.26 (13.6), 14.49 - 16.01 (15.3),
14 16.43 - 18.16 (17.3), 18.93 - 20.93 (19.9), 22.47 - 24.83 (23.6), 28.50 - 31.50 (30.0). The
15 subbands are marked in figures by their centre (mean) frequency values (see in brackets,
16 above). The terms “*lower*” and “*upper*” in “classical” EEG bands: *delta 1* (0.5 - 1.7 Hz), *delta*
17 *2* (2.1 - 3.5 Hz), *theta* (4.0 - 8.0 Hz), *alpha* (8.9 - 12.2 Hz), *beta1* (13.6 - 17.3) and *beta2*
18 (19.9 - 30.0), are used below to differentiate corresponding frequency subbands of each
19 band relative to its centre frequency.

20 The frequency spectra of 12-sec EEG epochs were averaged for every successive 10-min
21 interval in each mouse and for all similarly aged of him separately for nTg and Tg groups.
22 Relative differences in the averaged EEG spectra, obtained in the experiments with saline
23 (day 1) and APO (day 2) in each group, were normalized to corresponding baseline EEG
24 values and estimated as (APO - Saline) / Saline, in percentages, providing the evaluation of
25 APO effects.

26 2.3. Statistics

27 Differences in the EEG spectra averaged for 10 min in frames of “classical” frequency
28 bands were analyzed by ANOVA for repeated measures. To evaluate the EEG effects
29 progression in each of chosen band after APO and saline injections in different brain areas
30 and treatments or between them, one- or two-way ANOVA (with 10-min intervals as one of
31 repeated variables) were used, respectively. For multiple comparisons, Bonferroni post hoc
32 test was engaged. Results were considered statistically significant at $p < 0.05$. All data are
33 shown as mean \pm SEM. For ANOVA analyses, STATISTICA 10 (StatSoft, Inc., Tulsa, OK,
34 USA) was used.

35

36 3. Results

37 3.1. Baseline EEG from different brain areas

1 During baseline EEG recordings, both non-transgenic (nTg) and transgenic (Tg) $\Delta FUS(1-$
2 359) mice were behaviorally active and characterized by intensive exploration of the
3 experimental box that was very rarely (1-2/30 min) and stochastically interrupted by short
4 sleep-like bouts.

5 In younger (two-month old) nTg mice, baseline EEG from M1 and Pt demonstrated
6 patterns of relatively regular oscillations (Fig. 1, A), which were characterized by low-
7 amplitude *theta-alpha* peaks in their frequency spectra (Fig. 1, C – E, dashed lines). In EEG
8 from M1 in Tg mice no regular rhythms were observed (Fig 1, B) that was characterized by
9 relatively small peaks scattered over the representative example spectra (Fig., 1, C, E, solid
10 lines). In EEG from Pt in Tg mice, regular powerful high-frequency spindles were observed
11 (Fig. 1, B) that were manifested by large spectral peaks in beta band of the representative
12 example spectra (Fig. 1, D, F, solid lines). Averaged spectra of EEG recorded for three
13 consecutive 10-min intervals from the left M1 and Pt in younger nTg mice were characterized
14 by a wide peak in the range of *upper theta-alpha* (Fig. 2, A, C, dashed lines). In younger Tg
15 vs. nTg mice, spectral profiles of EEG from M1 were comparable, with exception of
16 enhanced *delta 2* (2-way ANOVA: $F_{1,42} = 4.3$, $p < 0.05$) and tended to be suppressed *upper*
17 *theta-alpha* in Tg mice (Fig. 2, A, grey bars). In Pt, the *theta* suppression and *beta 2*
18 enhancement in Tg vs. nTg mice reached significant levels (Fig. 2, C; 2-way ANOVA: $F_{1,42}$
19 $= 17.3$ and 10.2 , $p < 0.001$ and $p < 0.01$, respectively).

20 In older (five-month old) mice, the difference in Tg vs. nTg mice in the beta band was
21 observed in both M1 (Fig. 2, B; 2-way ANOVA: $F_{1,39} = 13.4$ and 13.3 , for *beta 1* and *beta 2*,
22 respectively, $p < 0.001$ for both) and Pt (Fig. 2, D; 2-way ANOVA: $F_{1,39} = 7.1$, $p < 0.05$, for
23 *beta 2*). These changes were combined with *delta 2* band suppression, which reached
24 significant values in M1 (2-way ANOVA: $F_{1,39} = 10.8$, $p < 0.01$). In the right hemisphere,
25 corresponding spectral profiles of EEG from M1 and Pt were similar to those observed in the
26 left hemisphere (c.f., Fig. 3 and Fig. 2). It should be mentioned that no interactions between
27 revealed significant EEG differences in Tg vs. nTg groups were observed for 30-min baseline
28 interval in mice of both ages that was confirmed by 2-way ANOVA ($F_{2,42} < 0.3$, $p > 0.7$ and
29 $F_{2,42} < 0.1$, $p > 0.9$, for younger and older mice, respectively). The differences were
30 characterized by reasonable power and effect size measures (see representative examples
31 of power analysis in Suppl. 3).

32 In the left hemisphere, evident M1 vs. Pt differences in EEG spectral profiles were
33 revealed in younger mice (Fig. 4, A, C). The inverse shapes of these relative spectral
34 characteristics in Tg and nTg mice were observed in *delta 2*, *theta*, *beta 1* and *beta 2* bands
35 (2-way ANOVA: $F_{1,39} = 30.5$, 21 , 13.1 and 24.9 , respectively, $p < 0.001$ for all). In the right
36 hemisphere (Fig. 4, C), similar differences were in *theta*, *beta 1* and *beta 2* bands (2-way
37 ANOVA: $F_{1,42} = 11$, $p < 0.01$, $F_{1,42} = 14.9$ and 15.2 , $p < 0.001$, respectively). In older vs.

1 younger mice, M1 vs. Pt differences in *delta 2* were inverted (Fig. 4, B; 2-way ANOVA: $F_{1,39}$
2 = 5.4, $p < 0.05$ and $F_{1,39} = 13.5$, $p < 0.001$ for the left and right hemispheres, respectively)
3 that was accompanied by increased *alpha* activity in the right M1 vs. Pt (2-way ANOVA:
4 $F_{1,39} = 12.9$, $p < 0.001$).

5

6 3.2. Apomorphine effects

7 After APO injection, behavioral reactions in both Tg and nTg mice were stereotyped:
8 short-lasting freezing (1.5-2 min), followed by uninterrupted licking of the floor and walls in
9 the box that was accompanied by tail erection. Sleep-like bouts were very rare and short,
10 and occurred at variable times in the second half of the experiment. Saline injection evoked
11 1-2-min explorative activation followed by a basic behavior typical for each individual mouse.

12 *Two-month old mice*

13 In two-month old (younger) nTg mice, APO (vs. saline) suppressed *delta 2* for 20 minutes
14 followed by its rising in EEG from the left M1 and Pt (Fig. 5, B and H, grey lines; 1-way
15 ANOVA: $F_{(5,42)}=3.5$, $p < 0.01$ and $F_{(5,42)}=3.2$, $p < 0.05$, respectively). (Here and below,
16 APO effects in the right hemisphere have been omitted because of their similarity to those in
17 the left side of the brain). After APO, *delta 2* changes in Tg mice did not reach significant
18 levels in M1 and Pt (Fig. 5, B and H, dark lines; 1-way ANOVA: $F_{(5,42)} < 0.6$, $p > 0.6$, for
19 both) and were significantly different from those in nTg mice (2-way ANOVA: $F_{(1,84)}= 2.4$
20 and 3.2, $p < 0.05$, for both). APO-evoked *theta* activity in EEG from M1 in Tg mice was more
21 powerfully expressed than in nTg mice (Fig. 5, C; 2-way ANOVA: $F_{(1,84)}= 21.9$, $p < 0.001$).
22 In Tg mice, similar effect in Pt (Fig. 5, I; 2-way ANOVA: $F_{(1,84)}= 4.9$, $p < 0.05$) was evidently
23 lesser than in the cortex (c.f., C and I in Fig. 5). Decreased sensitivity of M1 (vs. Pt) to APO
24 in Tg (vs. nTg) mice was expressed in significant suppression of APO effects in *beta 1* and
25 *beta 2* bands (Fig. 5, E and F; 2-way ANOVA: $F_{(1,84)}= 4.8$ and 6.1, respectively, $p < 0.05$,
26 for both.). In Pt, APO-evoked beta activity differences in nTg and Tg mice did not reach
27 significant levels (Fig. 5, K and L; 2-way ANOVA: $F_{(1,84)} < 2.4$, $p > 0.12$, for both).

28 *Five-month old mice*

29 In five-month old (older) nTg mice, APO (vs. saline) suppressed *delta 2* for 30 minutes
30 followed by its rising in EEG from the left M1 and Pt (Fig. 6, B and H, grey lines; 1-way
31 ANOVA: $F_{(5,36)}=3.3$, $p < 0.05$ and $F_{(5,42)}=4.5$, $p < 0.01$, respectively) with domination of
32 suppression in cortical and striatal EEG in nTg mice (2-way ANOVA: $F_{(1,78)} = 25.3$ and 23.3,
33 for M1 and Pt, respectively, $p < 0.001$, for both). APO-evoked *theta* activity in EEG from M1
34 and Pt in Tg mice was less powerfully expressed than in nTg mice (Fig. 5, C and I; 2-way
35 ANOVA: $F_{(1,78)}= 12.4$ and 6.5, for M1 and Pt, respectively, $p < 0.05$, for both). APO
36 produced gradual decline of *theta* activity in M1 and Pt in both groups with more powerful
37 expression in Tg mice (Fig. 6, D and J; 2-way ANOVA: $F_{(1,78)} = 10.9$, $p < 0.01$ and $F_{(1,78)} =$

1 4.8, $p < 0.05$, for M1 and Pt, respectively). Increased sensitivity of M1 (vs. Pt) to APO in Tg
2 (vs. nTg) mice was expressed in significant *beta 2* rising after APO injection (Fig. 6, F; 2-way
3 ANOVA: $F(1,78) = 9.8$, $p < 0.01$). In Pt, APO-evoked *beta 2* activity differences in nTg and Tg
4 mice did not reach significant levels (Fig. 6, L; 2-way ANOVA: $F(1,78) = 3.7$, $p = 0.06$). Thus,
5 in older (vs. younger) mice, APO differently affected *delta 2* and *alpha* activities in nTg and
6 Tg mice (c.f., B, D in figures 5 and 6) and inverted *theta* and *beta 2* effects in these groups
7 (c.f., C, F in figures 5 and 6). (All results of the ANOVA analyses have been summarized in
8 Suppl. 4, for clarity).

10 4. Discussion

11 In this study, we have shown significant differences between *FUS*-transgenic (Tg) and
12 non-transgenic (nTg) mice of different ages (two and five months) in baseline and
13 apomorphine-modified EEG recorded from primary motor cortex (M1) and putamen (Pt).

14 *Baseline EEG and cortex-striatum misbalance in ALS*

15 Averaged frequency spectra of baseline EEG from M1 of younger Tg mice were
16 practically similar to those in nTg littermates with exception of increased slow (*delta 2*)
17 oscillations in Tg mice (Fig. 2, A and Fig. 3, A) seemingly reflecting pathological state and
18 associated plasticity of their cortices [19]. In contrast, EEG from Pt in Tg vs. nTg mice were
19 characterized by suppressed *theta* and increased beta activities (Fig. 2, C and Fig. 3, C).
20 These differences were observed in older Tg mice in combination with *delta 2* suppression
21 predominantly in M1 (Fig. 2, B, D and Fig. 3, B, D). Together, these resulted in a cortex-
22 striatum misbalance in EEG spectral profiles at relatively early stage (two months) of
23 postnatal ALS progression with tendency to be similar to that in nTg mice at age of five
24 months (c.f., Fig. 4, A, C and Fig. 4, B, D, respectively) in spite of Tg vs. nTg differences in
25 EEG spectra from each of these structures (see Fig. 2, B and D). Thus, the cortex-striatum
26 misbalance might be considered, in first approximation, as a prognostic sign of early vs. late
27 stage of ALS pathology. In older Tg vs. nTg mice, suppressed *theta* in combination with
28 enhanced beta was observed in EEG from all brain areas (Fig. 2, B, D and Fig. 3, B, D).
29 Thus, alterations in cortical excitability in ALS are supposed to involve different neuronal
30 populations forming the cortical circuitry and varying at different disease stages [20 - 27].
31 Indeed, in older ALS mice, the enhanced *beta* activity was observed in EEG from both M1
32 and Pt, while at the early stage, this phenomenon was exclusively characteristic for Pt (Fig.
33 2). This is in line with an idea that developmental dysfunctions of striatal-cortical connections
34 may be one of the main causes of further movement disorders [23]. On the other hand, this
35 evidence might be supportive for a role of disturbances in *beta* oscillations supposedly
36 generating by autonomous subthalamic nucleus - globus pallidus external (STN - GPe)
37 mechanisms [24]. Finally, the composition of increased *beta* and suppressed *upper theta*-

1 *lower alpha* in the EEG spectra in Tg vs. nTg mice (Fig. 2, B – D and Fig. 3, B – D) might be
2 explained by ALS-associated imbalanced activity of circuits generating the fastest and slower
3 rhythms, respectively [25].

4 *Dopamine mediation in early ALS-associated EEG modifications*

5 The prevalence of beta oscillations in basal ganglia is linked with DA deficit in patients
6 with both Parkinson's and ALS diseases, and characterized by a loss of DA neurons in SN
7 and disintegration of nigrostriatal pathways [26 - 29]. These pathological processes revealed
8 in humans with ALS and in animal ALS models [30] are expected to result in chronic
9 depletion of DA in the terminal areas of M1 and Pt that in turn has to invoke both feed-back
10 and feed-forward mechanisms of supersensitization of DA receptors [31, 32]. Stimulation of
11 these receptors by residual DA has been shown to be able to maintain motor functions in
12 mice with developmental disturbances in the nigrostriatal system even at very low (< 5%) its
13 amount in the striatum [33]. Thus, *beta 2* rising in EEG from Pt in younger Tg mice (Fig. 2, C
14 and Fig. 3, C) seemingly highlights enhanced activation of DA receptors in this brain area at
15 early stage of ALS progression. This and *delta 2* domination in cortical EEG (Fig. 2, A and
16 Fig. 3, A), which is thought to reflect both pathological state and plasticity of the cortex [19],
17 characterize a misbalance in Pt and M1 electrical activities (Fig. 4, A, C), i.e. in their
18 functional states. Thus, the interstructural disturbances associated with sensitization
19 phenomena in DA mechanisms at early stage of ALS development might be provoking
20 factors for further deterioration of motor activity in the disease. In this respect, discovery of a
21 link between these mechanisms and genetic variants might be one of effective and
22 perspective approaches for understanding of molecular pathways involved in early stages of
23 diseases [34]. The similarity in spectral profiles of EEG interrelations between M1 and Pt,
24 which was observed at the late stage in both nTg and Tg mice (Fig. 4, B, D), seems to be
25 linked with the age-dependent DA receptor sensitization provoked by depletion of DA-
26 producing cell population [35 – 37]. Comparable levels of beta prevalence in EEG from M1
27 and Pt in older Tg vs. nTg mice (c.f., Fig. 2, B, D and Fig. 3, B, D, grey bars) are supportive
28 for this suggestion. Thus, the revelation of genetic aberrations associated with age-
29 dependent receptor sensitization could fill the gap between the early and late stages of
30 neurodegenerative pathologies. Below, the role of DA receptors in functioning of cortico-
31 striatal circuits is analyzed by use of apomorphine that is well known to activate
32 predominantly D2 receptors [12] involved in functioning of so-called "indirect" cortico-striatal
33 pathway [13].

34 *Apomorphine and EEG in ALS*

35 In younger (two-month old) nTg mice, APO (vs. saline) effects in both M1 and Pt were
36 phasic with initial 20-min suppression of *delta 2* and subsequent its enhancement (Fig. 5, B
37 and H, respectively). The profile of the APO effect evolution is in line with that observed in rat

1 cortical EEG [38] and with both brief (16-min) Tmax and relatively short (70-min) half-life of
2 APO in human blood plasma [39]. APO effects in *delta 2* band were accompanied by evident
3 *beta 2* domination picked in 30-40-min interval after APO injection (Fig. 5, F and L). APO-
4 produced suppression of cortical *beta 2* in Tg vs. nTg mice (Fig. 5, F) demonstrates robust
5 attenuation of DA receptors sensitivity in M1 whereas dimmed *beta 2* differences in Pt in Tg
6 and nTg groups (Fig. 5, L) seem to be associated with moderate changes in DA mediation.
7 And again, APO increased *theta* in Tg (vs. nTg) mice were more powerfully expressed in M1
8 than in Pt (c.f., Fig. 5, C and I). Thus, APO-produced stimulation of DA2 receptors at early
9 stage of ALS allows the revelation of some intimate processes in M1 that might be "hidden"
10 in baseline EEG spectra.

11 In older (five-month old) Tg vs. nTg mice, APO significantly enhanced *delta 2* in M1 and
12 Pt, *beta 2* in M1 and attenuated *theta* and *alpha* in both brain areas (see Fig. 6). Interestingly
13 that in older vs. younger mice, APO effects in *theta* and *beta 2* bands were inversed (c.f., Fig.
14 5, C, F and Fig. 6, C, F, respectively). This is supposedly linked with the developmental
15 changes in synaptic functioning associated with structural reorganization in motor cortex-
16 striatum interconnections and, possibly, with gradual loss of DA neurons in aging [28, 30].
17 Furthermore, an adaptive recovery of DA receptors sensitivity, which was disturbed by DA
18 neurons lost [31], might be involved in functioning of ALS-associated mechanisms as well [26
19 - 28].

20 If so, APO-enhanced cortical *theta* activity in *younger Tg* and *older nTg* mice (Fig. 5, C,
21 dark line and Fig. 6, C, grey line) may denote possible involvement of neuronal
22 hyperexcitability in mechanisms of both ALS and aging (see [40]). Given predominant role of
23 D2 receptors in APO effects [12], in regulation of neuronal activity in M1 [41], and in the
24 "indirect" cortical-striatal-cortical circuit functioning [13], it is reasonable suggest that D2
25 signaling in these neuronal circuits is principally important for *theta* activity regulation in EEG
26 from the brain areas involved [42, 43]. Indeed, in six-month old nTg mice with electrodes
27 implanted into the secondary motor cortex (M2), dorsal hippocampus (HPC) and DA-
28 producing nuclei: substantia nigra (SN) and ventral tegmental area (VTA), APO effects on
29 EEG spectral profiles have been shown [44] to be in some respects similar to those obtained
30 in current study. After APO injection, enhanced *beta 2* activity was observed in all brain
31 areas whereas *theta* was specifically increased in SN and VTA with characteristic gradual
32 slowing over time. Thus, in contrast to M1, APO-produced activation of D2 receptors was
33 unable to stimulate the release of *theta* oscillations in M2, despite its close vicinity to M1 that
34 might be linked with precise functional specialization of and interaction between different
35 cortical areas [45]. Growing evidence identifies the development of ALS disease in patients
36 and in ALS animal models with cognitive pathologies, in particular, with frontotemporal
37 dementia [46, 47]. The learning/memory mechanisms are well known to be closely linked

1 with EEG activity in the *theta* band [48]. Furthermore, ALS-provoking proteins (in particular,
2 *FUS*) have been shown to affect synaptic functions [49] allowing ALS to be considered as a
3 form of synaptopathy [50]. Given these, it is reasonable suggest that the reduced APO
4 efficacy in releasing *theta* activity in EEG from *five-month old* Tg vs. nTg mice (Fig. 6, C)
5 might be linked to the effects of ALS pathology on synaptic mechanisms of neuronal circuits
6 involved in cognitive functions. Finally, APO-enhanced *beta* activity in cortical EEG from both
7 *six-month old* nTg mice [37] and *five-month old* mice model of ALS in current study is thought
8 to be associated, respectively, with age- and ALS-dependent enhancement of D2 receptors
9 sensitivity in cortico-striatal "*indirect*" pathway involving its intrinsic (STN - GPe) pacemaker
10 of beta oscillations [24]. Age-dependent shifts in VTA and SN neuronal firing from pacemaker
11 to *random* mode, and then to *bursting* mode [51] could be a part of the adaptive mechanisms
12 in regulation of motor function. Thus, APO modifications of spectral profiles of EEG from VTA
13 and SN [44] provide additional revelation (vs. that of baseline EEG) of modified DA receptor
14 sensitivity associated with mechanisms of *tonic (delta)* suppression and *bursting (beta 2)*
15 enhancement in neuronal activities in the DA-producing areas.

16 Conclusion. We have shown that evident spectral differences between younger (two-
17 month old) *FUS* and non-transgenic mice were observed in baseline EEG predominantly
18 from their striatal *n. putamen* rather than from the motor cortex, whereas in older (five-month
19 old) mice, the spectral profiles of EEG from both brain areas were similar (Fig. 2 and Fig. 3).
20 Thus, ALS development is associated with initial pathological changes in the striatum (*n.*
21 *putamen*) followed by those in the motor cortex. These result in evident abnormalities in
22 cortex-putamen EEG interrelations extremely expressed at early stage of ALS (Fig. 4). The
23 most evident changes, associated with developmental processes, were revealed in *delta 2*,
24 *theta* and *beta 2* bands. In total, our data are supportive for EEG frequency spectra as an
25 effective marker of ALS disease [52]. Furthermore, the "pharmaco-EEG" approach used in
26 our study is suggested to open the missing gate for studying intermediate phenomena in ALS
27 development, which are situated between the well-characterized disturbances in movement
28 and cellular processes [53]. It might be a useful tool for further studies of the neuronal
29 network remodeling [54] associated with ALS developmental structural and functional
30 disturbances in interrelations between different cerebral systems.

3 **Figure 1.** Typical patterns in 12-s fragments of baseline EEG in wakeful and behaviourally
4 active non-transgenic (nTg) and *FUS*-transgenic (Tg) two-month age mice (A and B,
5 respectively) and their frequency spectra (C - F) in the primary motor cortex (M1) and
6 putamen (Pt) in the left (sin) and right (dex) brain hemispheres. On A and B, time calibration
7 is 1 sec, amplitude calibration is 100 μ V. On C - F, abscissa is a frequency subband marked
8 with its mean value, in hertz; ordinate is summed amplitude of EEG in each of 25 subbands,
9 normalized to a sum of all amplitude values, in arbitrary units. Four vertical lines separate
10 "classical" EEG frequency bands.

11

12 **Figure 2.** Averaged amplitude-frequency spectra of 12-s baseline EEG fragments recorded
13 from the left primary motor cortex (A, B) and putamen (C, D) for 60 min in non-transgenic
14 (nTg) and *FUS*-transgenic (Tg) mice (dashed and solid lines, respectively) at different ages
15 (two- and five-months, $n = 8$ and 7 ; A, C and B, D, respectively) and spectral ratios (narrow
16 grey bars) between the groups (Tg/nTg). Abscissa is a frequency subband marked with its
17 mean value, in hertz; the left ordinate is summed absolute values of EEG amplitudes in each
18 of 25 subbands, normalized to sum of all amplitude values, in arbitrary units; the right
19 ordinate is a ratio of the EEG amplitudes, calculated as $(Tg - nTg) / nTg$, in %. Error bars
20 show ± 1 SEM. Four vertical lines separate "classical" EEG frequency bands where asterisks
21 denote ANOVA significant differences between Tg and nTg groups: * - $p < 0.05$, ** - $p < 0.01$,
22 *** - $p < 0.001$.

23

24 **Figure 3.** Averaged amplitude-frequency spectra of 12-s baseline EEG fragments recorded
25 from the right primary motor cortex (A, B) and putamen (C, D) for 60 min in non-transgenic
26 (nTg) and *FUS*-transgenic (Tg) mice (dashed and solid lines, respectively) at different ages
27 (two- and five-months, $n = 8$ and 7 ; A, C and B, D, respectively) and spectral ratios (narrow
28 grey bars) between the groups (Tg/nTg). Abscissa is a frequency subband marked with its
29 mean value, in hertz; the left ordinate is summed absolute values of EEG amplitudes in each
30 of 25 subbands, normalized to sum of all amplitude values, in arbitrary units; the right
31 ordinate is a ratio of the EEG amplitudes, calculated as $(Tg - nTg) / nTg$, in %. Error bars
32 show ± 1 SEM. Four vertical lines separate "classical" EEG frequency bands where asterisks
33 denote ANOVA significant differences between Tg and nTg groups: * - $p < 0.05$, ** - $p < 0.01$,
34 *** - $p < 0.001$.

35

36 **Figure 4.** Relations between averaged amplitude-frequency spectra of 12-s baseline EEG
37 fragments recorded from the primary motor cortex (M1) and putamen (Pt) for 60 min in non-

1 transgenic (nTg) and FUS-transgenic (Tg) mice (dashed and solid lines, respectively).
2 Abscissa is a frequency subband marked with its mean value in hertz; ordinate is a ratio of
3 summed absolute values of baseline EEG amplitudes in each of 25 subbands, normalized to
4 sum of all amplitudes of EEG recorded from M1 and Pt, calculated as $(M1 - Pt) / Pt$, in %,
5 characterizing genetically determined EEG relations between them. Error bars show ± 1
6 SEM. Four vertical lines separate "classical" EEG frequency bands where asterisks denote
7 ANOVA significant differences between Tg and nTg groups: ** - $p < 0.01$, *** - $p < 0.001$.

8

9 **Figure 5.** Evolution of apomorphine (APO, 1.0 mg/kg, s.c.) vs. saline effects in different
10 frequency bands of EEG from the left M1 and Pt in two-month old *FUS* and non-transgenic
11 mice (dark and grey lines, respectively; $n = 8$ in each group). Abscissa shows time after
12 injection marked in 10-min intervals. Ordinate is a ratio of the EEG amplitudes, calculated as
13 $(APO - \text{saline}) / \text{saline}$, in %, separately for nTg and FUS mice (grey and dark lines,
14 respectively) and normalized to baseline EEG ratios (horizontal dashed lines). Error bars
15 show ± 1 SEM.

16

17 **Figure 6.** Evolution of apomorphine (APO, 1.0 mg/kg, s.c.) vs. saline effects in different
18 frequency bands of EEG from the left M1 and Pt in five-month old *FUS* and non-transgenic
19 mice (dark and grey lines, respectively; $n = 8$ in each group). Abscissa shows time after
20 injection marked in 10-min intervals. Ordinate is a ratio of the EEG amplitudes, calculated as
21 $(APO - \text{saline}) / \text{saline}$, in %, separately for nTg and FUS mice (grey and dark lines,
22 respectively) and normalized to baseline EEG ratios (horizontal dashed lines). Error bars
23 show ± 1 SEM.
