Reduced serum vitamin B-12 in patients taking metformin

Until the clinical importance is clear, simple dietary advice could solve the problem

As many as 22% of people with type 2 diabetes could have vitamin B-12 deficiency. The cause of vitamin B-12 deficiency in these patients remains controversial, but it can have important consequences and should be considered in the differential diagnosis of diabetic neuropathy. In small short term studies, treatment with metformin has been associated with reduced vitamin B-12 concentrations and an increased risk of vitamin B-12 deficiency. Kooi and colleagues conducted a trial of the long term effects of metformin treatment on metabolic and microvascular and macrovascular complications in patients with type 2 diabetes who were already taking insulin. Three hundred and ninety patients were randomised to receive insulin plus metformin or insulin plus placebo. After a follow-up of 4.3 years, the study found fewer macrovascular events in the metformin group, which was largely accounted for by the beneficial effect of metformin on weight. In the linked study this same group of authors, but with de Jager as first author, perform a further analysis of their earlier study and report important differences in serum vitamin B-12 in participants. In the placebo group, vitamin B-12 increased by 0.2 pmol/l (0%, 95% confidence interval –3% to 4%), whereas in the group with the addition of metformin vitamin B-12 was reduced by 89.8 pmol/l (–19%, –22% to –15%). At baseline, three participants in the metformin group and four in the placebo group had vitamin B-12 concentrations below 150 pmol/l. At follow-up after 4.3 years this had increased to 19 and five participants, respectively. The reduction in concentrations of vitamin B-12 in the metformin group persisted and become more apparent over time. The number needed to harm per 4.3 years was 13.8.

Although the absolute number of affected participants was small the differences in vitamin B-12 concentrations are convincing. A strength of this study is the long period of follow-up.

The authors recommend that regular measurement of vitamin B-12 concentrations during long term metformin treatment should be considered. Sadly, though, they do not report on quality of life, neurological status, or measures of fatigue. Neither do they report whether participants received any dietary advice regarding vitamin B-12. As their introduction makes clear, we have no robust research underpinning the assumption that people with vitamin B-12 concentrations of 150 pmol/l or less are indeed vitamin B-12 deficient. Although they may be at higher risk for vitamin B-12 deficiency related effects, these risks are not clearly quantified or always directly related to vitamin B-12 concentrations. An opportunity may have been missed to elucidate whether reduced vitamin B-12 concentrations resulted in meaningful symptoms. Were the participants with lower concentrations of vitamin B-12 more likely to feel worse and have adverse effects?

Other uncertainties include whether or not these findings apply to most patients managed in primary care, who are not usually treated with insulin—should these patients also be monitored for vitamin B-12 concentrations? The conversion of patients with type 2 diabetes to insulin treatment is controversial, and it is the minority of patients whose diabetes is hardest to control who typically start insulin treatment. If patients are monitored, how should serum vitamin B-12 be measured? Furthermore, it is not clear what form the intervention should take. The options include dietary advice; increase intake of foods rich in calcium and vitamin B-12; and vitamin B-12 supplements, which could be taken orally or injected—most patients will not have problems absorbing vitamin B-12 from the gut because this form of vitamin B-12 deficiency is unlikely to be related to intrinsic factor or bowel disease. There are several other questions related to vitamin B-12 replacement. Given the long time it takes to deplete vitamin B-12 stores, how often—if at all—would intramuscular injections need to be repeated? Should concentrations be monitored once treatment is started? Can treatment be stopped after dietary improvement? Would we miss important morbidity by proceeding on the basis of symptoms and heightened clinical suspicion rather than on systematic screening in all patients taking metformin?

The case that de Jager and colleagues make for routine assessment of serum vitamin B-12 concentrations is based on findings from patients taking insulin and with no evidence that monitoring will benefit patients. The mechanisms are unclear, but it could be something as simple as the dietary change associated with metformin. We first need to determine whether simple dietary counselling when metformin is started and at medication/annual reviews will solve the problem. If it does not, a trial of screening for vitamin B-12 deficiency in patients taking metformin would be needed. Patients taking metformin (not just those also treated with insulin) should be randomised to systematic serum vitamin B-12 screening or routine care, with patient oriented outcomes and costs included in the outcomes. Otherwise, we risk increasing the burden on patients and the costs of care by treating biochemical outcomes rather than outcomes that matter to patients.
Diagnosing diabetes using glycated haemoglobin A1c

Could have several advantages over traditional diagnostic methods

Diabetes is one of the three most prevalent chronic diseases that pose serious threats to health. A recent study of 66,239 Chinese people aged 20 years or more indicated a prevalence of diabetes and prediabetes (blood glucose between normal and diabetic values) of 9.7% and 15.5%, respectively. These figures translate into a total of 92.4 million people in China with diabetes. In the linked study, Bao and colleagues assess the value of glycated haemoglobin A1c (HbA1c) in diagnosing diabetes and identify the optimal HbA1c cut-off value to be used in Chinese adults.

Currently, fasting plasma glucose values and the oral glucose tolerance test are most commonly used for the screening and diagnosis of diabetes. However, both require a fast of at least eight hours, and the oral glucose tolerance test also requires multiple blood collections, aspects that reduce patient compliance and limit their clinical application.

Recently, HbA1c, a measure of long term glycaemic control, has been suggested as an alternative tool for diagnosing diabetes. Because HbA1c values are proportional to the mean blood glucose concentration over the previous two to three months, patients do not need to fast, making these tests convenient and easy to perform.

In June 2009, an international expert committee consisting of members from the American Diabetes Association, the European Association for the Study of Diabetes, and the International Diabetes Federation published a report recommending the use of an HbA1c value of 6.5% or more as a diagnostic criterion for diabetes. In the latest 2010 version of Standards of Medical Care in Diabetes released by the American Diabetes Association, HbA1c values of 6.5% or more and of 5.7% or more are recommended as diagnostic and screening criteria for diabetes, respectively. Similarly, a recent community based study assessing the validity of HbA1c for the diagnosis of diabetes in Asian Indians proposed that HbA1c thresholds of 6.1% and 6.5% could be used as screening and diagnostic tests for diabetes, respectively. Previous studies have shown, however, that the optimal cut-off point of HbA1c for detecting diabetes may vary by racial or ethnic group.

Little information regarding the usefulness of HbA1c tests in the diagnosis of diabetes is available for Chinese populations. In the linked cross sectional survey Bao and colleagues assess the usefulness of HbA1c as a screening and diagnostic tool for diabetes compared with fasting plasma glucose concentrations and the oral glucose tolerance test in 4,900 Chinese adults with no history of diabetes. Their results suggest that for those at high risk for diabetes, an HbA1c cut-off value of 6.3% or more had a significantly higher sensitivity than fasting plasma glucose at 7.0 mmol/l or more and of the generally suggested HbA1c threshold of 6.5% or more. HbA1c therefore provides an alternative method for screening and diagnosing diabetes in the clinical setting. Furthermore, HbA1c can be sampled at any time, improving patient compliance and enabling timely diagnosis of people who do not meet the criteria for fasting and those who are unwilling to take the oral glucose tolerance test.

Currently, most general hospitals in China can carry out HbA1c tests. In addition, the Chinese Ministry of Health is implementing a quality control system for HbA1c tests. The study by Bao and colleagues established an optimal HbA1c cut-off value of 6.3% or more as a diagnostic criterion for diabetes in Chinese adults. Nevertheless, further epidemiological and clinical studies on a larger scale, particularly prospective ones, are needed to validate the efficacy of HbA1c for diagnosing diabetes, and to tackle the association of HbA1c diagnostic cut-off points with chronic complications of diabetes, such as retinopathy.

HIV transmission in serodiscordant heterosexual couples

Risk is not zero but is low if the infected partner takes antiretrovirals

Antiretroviral treatment inhibits HIV viral replication and reduces plasma viral load. Low plasma viral load is associated with a lower probability of HIV transmission, which opens the possibility of treatment to reduce HIV transmission.1 2 The feasibility, potential effectiveness, and risks of such treatment are unclear, and a key uncertainty is the extent to which successful antiretroviral treatment reduces HIV infectivity. In the linked observational study, Del Romero and colleagues estimate the risk of heterosexual transmission of HIV from infected people taking combined antiretroviral treatment.3

Only randomised controlled trials comparing transmission in HIV serodiscordant couples, where the infected (index) partner receives or does not receive antiretroviral drugs, can accurately estimate the effect of such treatment on infectivity. The HPTN-052 trial is the only ongoing trial of this type. In this trial, partners infected with HIV are assigned to immediate antiretroviral treatment or deferred treatment when their CD4 count drops below 250 cells/μl. This trial will hopefully provide a good estimate of the effect of antiretroviral treatment in patients with more than 250 CD4 cells/μl, but it will obviously not obtain an estimate in patients with fewer than 250 CD4 cells/μl.

Evidence that antiretroviral treatment reduces sexual transmission of HIV comes from observational studies of serodiscordant couples and ecological studies,2 4 5 but transmission from patients on antiretroviral treatment has also been documented.4 Del Romero and colleagues’ study is a welcome addition to the observational studies that estimate infectivity in serodiscordant couples. In partners of patients with HIV not receiving treatment, the incidence of HIV was 0.6 per 100 couple years, whereas none of the partners of patients on antiretroviral treatment seroconverted. The authors also computed the probability of transmission per unprotected sex act (figure). The infectivity estimates were low and imprecise, with no significant difference between treated and untreated patients (figs 1 and 2, see bmj.com). The authors therefore conclude that transmission of HIV from successfully treated patients cannot be excluded, because it is biologically possible and because the data are consistent with one infection per 91 couple years (compared with one per 71 couple years in untreated couples). Moreover, because this is an observational study, the treated and non-treated groups are most probably not comparable. Patients receiving treatment are necessarily different because of their poorer clinical history. Some differences were also seen in risk behaviour and characteristics of the index partners at baseline and during follow-up, which may have increased transmission in couples with an untreated index partner.1

How do the results of Del Romero’s study compare with other studies? Apart from four studies from high income countries conducted before the era of antiretroviral treatment that also reported no seroconversion, the infectivity estimates in the non-treated group were generally lower in Del Romero’s study than in previous studies.1 7 8 A recent systematic review of observational studies in heterosexual serodiscordant couples found five studies reporting HIV infectivity estimates according to treatment. In two of these studies with information on viral load, no seroconversions were seen when treated index patients had viral loads of fewer than 400 copies/ml. One study from Uganda reported no seroconversions in partners of treated cases despite only 79% having achieved a viral load fewer than 400 copies/ml six months after the start of treatment. A more recent study (not in the systematic review) in seven African countries observed one seroconversion in 256 person years of follow-up in partners of index cases.9

Together, these seven studies of patients receiving antiretroviral treatment independently of viral load will help to provide a more precise overall estimate of the seroconversion rate.4 10 Although the probability of transmission during antiretroviral treatment seems to be greater than zero, these studies support the idea that treatment reduces infectivity, which could translate into benefits at the population level, as long as risk behaviour does not increase. To date, some studies,5 but not all,10 suggest a beneficial effect of antiretroviral treatment at the community level.

What effect do these data have on counselling serodiscordant couples? In 2008, the Swiss Federal AIDS Commission released a controversial statement to the effect that HIV infected people with undetectable concentrations of the virus (<40 copies/ml) for at least six months, who adhered to a strict antiretroviral drug programme and had no other sexually transmitted infections, were not infectious to their regular heterosexual partners.11 The challenge for counsellors is to ensure that people understand the exact set of conditions and time period when it seems to be safe to have unprotected sex. Del

Wellbeing in the workplace
Lack of precise measurement or recommendations should not deter employers from taking action

In November 2009, the National Institute for Health and Clinical Excellence (NICE) published guidance for employers on promoting mental wellbeing through productive and healthy working conditions.1 Excess work related stress harms employees’ physical and mental health. From an economic perspective, impaired efficiency at work associated with mental health problems costs the United Kingdom £15.1bn (£16.9bn; $22.2bn) a year.1 From a health perspective, stress at work is consistently associated with increased total mortality and acute myocardial infarction.2,4

Ideally, the guidelines should outline discrete steps that could easily be implemented, improve the efficiency and satisfaction of workers, and ultimately be shown in a randomised controlled trial to improve morbidity and mortality. Although the guidance falls short of this ideal, business managers and human resources departments may still benefit from the advice.

Unfortunately, some of the advice is so general that it is almost useless. For example, the first recommendation in the guidance is to: “Adopt an organisation-wide approach to promoting the mental wellbeing of all employees, working in partnership with them. This approach should integrate the promotion of mental wellbeing into all policies and practices concerned with managing people, including those related to employment rights and working conditions.” This reads more like a mission statement than a discrete step that a responsible business manager could implement. Other recommendations are more practical, however; examples of how to monitor mental wellbeing (such as attitude or satisfaction surveys, and data on absence rates and employee turnover) are reasonable and appropriate for different sized businesses. Other advice, such as allowing workers flexible hours, and that managers “respond with sensitivity to employees’ emotional concerns” may seem to lag behind policies already in place in many human resource departments.

Perhaps the lack of concrete guidance comes from the diverse and changing nature of stress. Stress is not easy to measure—after all, it is subjective. The NICE guidance defines stress as “the adverse reaction people have to excessive pressure or other types of demand placed on them,” which may seem to lag behind policies already in place in many human resource departments.

Acupuncture transmitted infections

Acupuncture transmitted infections are underdiagnosed, so clinicians should have a high index of suspicion.

Acupuncture, which is based on the theory that inserting and manipulating fine needles at specific acupuncture points located in a network of meridians will promote the harmonious flow of “Qi,” is one of the most widely practised modalities of alternative medicine. Because needles are inserted up to several centimetres beneath the skin, acupuncture may pose risks to patients. One of the most important complications is transmission of pathogenic micro-organisms, from environment to patient or from one patient to another.

In the 1970s and 1980s most infections associated with acupuncture were sporadic cases involving pyogenic bacteria. If so far, more than 50 cases have been described globally. In most cases, pyogenic bacteria were transmitted from the patient’s skin flora or the environment because of inadequate skin disinfection before acupuncture.

Physically inactive can be measured using a pedometer, which can be provided to each employee with encouragement to walk for 30 minutes every day. Smoking can be measured by cotinine concentrations and banned on premises, and there could be a ban on hiring smokers (allowable in 39 US states). Unhealthy eating and obesity can be monitored through body mass index, waist size, and portion sizes. People can be advised to eat five servings of fruits and vegetables a day, and the organisation can help them do this by making healthy food available and unhealthy food less so. Alcohol intake can be quantified.

Evidence shows that programmes to manage stress in the workplace have beneficial effects. Much of the best work in this field comes from Japan, where workplace stress is high—more than 60% of Japanese workers report high levels of anxiety and stress. Two recent randomised controlled trials showed that single session educational programmes for supervisors, compared with no programme, can significantly improve knowledge, reduce psychological distress in workers, and improve job performance. One programme that taught stress management in hospitals decreased the frequency of malpractice claims (arguably a proxy in the United States for preventable medical errors) in 22 hospitals by 71% compared with a 3% decrease in hospitals without a stress management programme. Such a programme also decreased physician (and nurse) burnout and improved physician (and nurse) satisfaction with work.

The NICE guidance implies that the difficulty in measuring stress should not deter organisations from trying to reduce it. Organisations will be more successful if employees help their workers to manage stress.

The science of reducing stress in the workplace is in its infancy, and completing the circle from business policies to improved clinical outcomes is far away. In the meantime, the NICE guidelines can provide some basic advice for businesses wishing to make an impact on productivity and their employees’ health.

Provenance and peer review: Commissioned; not externally peer reviewed.

of the infections and at least another 10% had serious consequences such as joint destruction, paraplegia, necrotising fasciitis, and multiorgan failure.12

Apart from pyogenic bacterial infections, five outbreaks of hepatitis B virus infection associated with acupuncture, which affected more than 80 patients, have been described globally since the 1970s.14 In most outbreaks the sources were infected patients, and the virus was transmitted from one patient to another through improperly sterilised or unsterilised reusable acupuncture needles, but in one outbreak an acupuncturist who was positive for hepatitis B surface antigen and hepatitis B e antigen was thought to be the source.5 6

The other two major blood borne viruses, hepatitis C virus and HIV, could hypothetically be transmitted by acupuncture. Most evidence for the association of hepatitis C virus infection with acupuncture came from epidemiological and case-control studies, where acupuncture was found to be an independent risk factor for hepatitis C virus infections.7 Although no clear evidence exists to support a link between acupuncture and HIV infection, there are reports of patients with HIV who had no risk factors other than acupuncture.8

A new clinical syndrome has emerged in the 21st century—acupuncture mycobacteriosis—which is mainly caused by rapidly growing mycobacteria. A These mycobacteria are thought to be transmitted from the environment to patients via contaminated equipment used in acupuncture, such as cottonwool swabs, towels, hot pack covers, and boiling tanks. All mycobacterial infections associated with acupuncture so far have been characterised by localised meridian specific and acupuncture point specific lesions without dissemination.8 9 10 The lesions usually first appear as erythematous papules and nodules that subsequently develop into large pustules, abscesses, and ulcerative lesions after several weeks to months. Patients tended to delay seeking medical advice because of the slowly developing and relatively mild symptoms. Owing to the relatively hardy nature of mycobacteria,10 the long incubation period of the infection, and the difficulty in making a diagnosis, mycobacteria have caused two large outbreaks associated with acupuncture, which affected more than 70 patients.11 12

The case reports and outbreaks of acupuncture transmitted infections may be the tip of the iceberg. The first reports of meticillin resistant S aureus (MRSA) transmitted by acupuncture appeared in 2009.12 The emergence of community associated MRSA infections may aggravate the problem. To prevent infections transmitted by acupuncture, infection control measures should be implemented, such as use of disposable needles, skin disinfection procedures, and aseptic techniques. Stricter regulation and accreditation requirements are also needed.

Clinicians should also have a high index of suspicion, particularly for viral and mycobacterial infections transmitted by acupuncture because of their prolonged incubation periods, and they should alert health authorities about clusters of cases.
