Intermediate water links to Deep Western Boundary Current variability in the subtropical NW Atlantic during marine isotope stages 5 and 4

H. K. Evans, I. R. Hall, G. G. Bianchi, and D. W. Oppo

Received 21 December 2006; accepted 24 April 2007; published 2 August 2007.

[1] Records from Ocean Drilling Program Sites 1057 and 1059 (2584 m and 2985 m water depth, respectively) have been used to reconstruct the behavior of the Deep Western Boundary Current (DWBC) on the Blake Outer Ridge (BOR) from 130 to 60 kyr B.P. (marine isotope stage (MIS) 5 and the 5/4 transition). Site 1057 lies within Labrador Sea Water (LSW) but close to the present-day boundary with Lower North Atlantic Deep Water (LNADW), while Site 1059 lies within LNADW. High-resolution sortable silt mean (SS) grain size and benthic δ13C records were obtained, and changes in the DWBC intensity and spatial variability were inferred. Comparisons are made with similar proxy records generated for the Holocene from equivalent depth cores on the BOR. During MIS 5e, SS evidence at Site 1057 suggests slower relative flow speeds consistent with a weakening and a possible shoaling of the LSW-sourced shallower limb of the DWBC that occupies these depths today. In contrast, the paleocurrent record from the deeper site suggests that the fast flowing deep core of the DWBC was located close to its modern depth below 3500 m. During this interval the benthic δ13C suggests little chemical stratification of the water column and the presence of a near-uniform LNADW-dominated water mass. After ~111 kyr B.P. the SS record at Site 1057 increases to reach values similar to Site 1059 for the rest of MIS 5. The strengthening of flow speeds at the shallow site may correspond to the initiation of Glacial North Atlantic Intermediate Water formation also suggested by a divergence in the benthic δ13C records with Site 1057 values increasing to ~1.2‰. Coupled suborbital oscillations in DWBC flow variability and paleohydrography persisted throughout MIS 5. Comparison of these data with planktonic δ18O records from the sites and alkenone-derived sea surface temperature (SST) estimates from the nearby Bermuda Rise suggest a hitherto unrecognized degree of linkage between oscillations in subtropical North Atlantic SST and DWBC flow.

1. Introduction

[2] The Atlantic Meridional Overturning Circulation (AMOC) is responsible for a substantial component of the meridional heat transport in the Atlantic Ocean [e.g., Ganachaud and Wunsch, 2000] and abrupt shifts of the AMOC are considered to have played a key role in driving the dramatic and rapid climate variability during the last glacial period [Clark et al., 2002 and references therein]. Initiation of the AMOC occurs through the production of North Atlantic Deep Water (NADW), which consists of two main components: cold and dense Lower North Atlantic Deep Water (LNADW) forming the deepest layer and Labrador Sea Water (LSW, also known as upper NADW) at an intermediate level. The renewal of LNADW is fed by the overflow of intermediate depth water formed following the convection of surface ocean waters in the Greenland, Iceland, and Norwegian (GIN) Seas [Aagaard et al., 1985; Mauritzen, 1996]. About 3.2 Sv (~10^8 m^3 s^-1) of northern source water passes between Iceland and Scotland [Saunders, 1996]. In addition, a nearly equal volume of slightly colder waters pass over the shallow sill in the Denmark Strait [Dickson and Brown, 1994]. These waters form the Atlantic Deep Western Boundary Current (DWBC) along the continental slope east of Greenland. As the DWBC flows south, it encounters LSW formed by winter time convection of surface waters to an estimated depth of ~1,500 m in the central Labrador Sea [Reid, 1994]. Some LSW which is warmer, less saline, and less dense than LNADW [Dickson and Brown, 1994] is entrained by the DWBC, which transports about 13–14 Sv of NADW equatorward [Talley and McCartney, 1982; Schmitz and McCartney, 1993]. During its passage it is progressively undercut by northward flowing colder and denser Southern Ocean waters (Antarctic Bottom Water, AABW). The intensity and flow characteristics of the DWBC are known to have varied in space (depth) and time, which is believed to be a response to...
changes in source water production [Pickart, 1992; Bianchi et al., 2001].

Paleoceanographic reconstructions of past variability in the contribution of intermediate and deepwater masses in the North Atlantic are mainly based on the geochemical analyses of epifaunal benthic foraminifera. Such work is aimed at the proxy determination of the paleohydrography or paleobiogeochemistry (e.g., nutrient content) of the waters inhabited by these organisms whose shell chemistry is believed to reflect the chemistry of the bottom waters they have lived in. This method is particularly useful to detect the changing proportion of NADW and poorly ventilated AABW. The most widely employed nutrient proxy is the ratio of stable carbon isotopes of benthic foraminiferal calcite [e.g., Curry et al., 1988; Duplessy et al., 1988; Curry and Oppo, 2005]. This approach is based on the observation that the $\delta^{13}$C of $\Sigma$CO$_2$ dissolved in seawater displays a distribution in the world ocean that resembles the distribution of the main global water masses [Kroopnick, 1985]. Biological nutrient cycling results in low $\delta^{13}$C in nutrient rich waters like those derived from the Southern Ocean and high $\delta^{13}$C in nutrient poor waters like those formed in the North Atlantic today. Carbon isotope gradients in the world’s ocean reflect mixing between water masses and progressive oxidation of low-$\delta^{13}$C organic matter. The application of $\delta^{13}$C methods, in addition to other nutrient proxies such as Cd/Ca [e.g., Boyle, 1988; Boyle and Keigwin, 1982], have established that circulation patterns in the Atlantic were significantly different during glacial times. Northern source waters sank only to intermediate depths, forming the so-called Glacial North Atlantic Intermediate Water (GNAIW), resulting in a shoaling of the Atlantic deepwater core layer to approximately 2000 m, from 3000 m during interglacials [Boyle and Keigwin, 1987; Duplessy et al., 1988; Curry and Oppo, 2005]. Dense southern waters filled the deep glacial Atlantic below GNAIW [Boyle and Keigwin, 1987; Duplessy et al., 1988; Sarthein et al., 1994; Curry and Oppo 2005]. However, occasional differences between estimated nutrient changes derived from benthic $\delta^{13}$C measurements suggest that variations in isotope fractionation during air-sea exchange [Broecker and Maier-Reimer, 1992; Charles et al., 1995; Lynch-Stieglitz et al., 1996, 1999; Oppo and Horowitz, 2000] and/or marine biological productivity [Mackensen et al., 2001] may also contributed to the changes in the benthic $\delta^{13}$C signal. In addition to the complications in interpreting $\delta^{13}$C mentioned above, neither benthic $\delta^{13}$C nor Cd/Ca are conservative tracers, and therefore complementary methods (ideally not linked with the ocean’s biogeochemical cycle) are required to reconstruct past changes in ocean circulation. One of these methods is sedimentological and quite distinct from geochemical proxies, as it provides physical evidence for relative changes in the intensity of the near-bottom water flow. The parameter used is the sortable silt (SS), the mean grain size of the 10–63 $\mu$m terrigenous sediment subfraction [McCave et al., 1995; McCave and Hall, 2006]. From modern hydrographic investigations, it is clear that there is a link between the hydrographic location of NADW and vigorous deepwater circulation [Stahr and Sanford, 1999]. However, the hydrographic signal is more likely to be geographically widespread whereas the intensity of the DWBC will be more variable because of its interactions with local bathymetry [McCave and Hall, 2006].

Here we focus on reconstructing changes in the hydrography and near-bottom flow speeds of the DWBC bathing the Blake Outer Ridge (BOR) in the western subtropical North Atlantic at intermediate water depths during marine isotope stage (MIS) 5 and into MIS 4 (~130–60 kyr) and compare this with the Holocene. The study sites are ideally located to monitor changes in the relative intensity of LNDW and LSW, a water mass whose contribution to the overall fluctuations in the AMOC over the last glacial-interglacial period remains poorly understood [e.g., Hillaire-Marcel et al., 2001; Rasmussen et al., 2003].

2. Regional Setting

The Blake Outer Ridge is a constructional sedimentary drift that protrudes out of the continental shelf south of Cape Hatteras and north of the Bahama Islands. It forms a continuous extension of the eastern continental margin of North America (Figure 1) and was molded by the deep contour-following bottom currents of the DWBC [Flood, 1979]. The 700-km-long BOR slopes to the southeast between ~2000 and 5000 m water depth and is believed to have formed through interaction between the upper part of the DWBC and the lower part of the Gulf Stream (Florida Current) where it detaches from the continental shelf [Bryan, 1970; Stahr and Sanford, 1999]. These currents erode and transport sediments originating from the continental margin to the north and Blake Plateau to the south respectively [Ewing et al., 1966; Heezen et al., 1966; Laine et al., 1994]. Amos et al. [1971] found that the BOR diverted the DWBC and its fast moving core away from the western boundary, but once the DWBC rounded the deeper reaches of the ridge it flowed westward to the Blake Escarpment, before once again flowing equatorward.

The depth range spanned by the BOR means that current-controlled sediment deposition occurs under the influence of each of the climatically important water masses which make up the DWBC. Stahr and Sanford [1999] subdivided the present-day water column that influences sedimentation on the BOR into four main water masses: the uppermost water mass is a shallow component of Labrador Sea Water (LSW, 1000–1800 m water depth), this is underlain by LNDW (1400–2800 m water depth), LNADW (2500–4100 m water depth) and deep Bottom Water (BW, >3400 m water depth to the bottom) (see Table 1). This latter water mass consists of a varying mixture of northern (84–90%) and southern (10–16%) source waters [Stahr and Sanford, 1999]. The water depths of these boundaries overlie each other reflecting a deepening of the DWBC flow along the ridge crest and that these categories are partly based on an amalgamation of prior definitions [Stahr and Sanford, 1999].

Absolute velocity profiles along the eastern flank of the BOR [Stahr and Sanford, 1999] demonstrate that the
present-day fast flowing primary core of the DWBC is located between 3500 m water depth near the upstream origin of the BOR and 4100 m further downstream along the ridge. *Johns et al.* [1997] and *Stahr and Sanford* [1999] also document a secondary fast flowing core within SLSW between 4°C and 6°C (1000–1800 m water depth) which is less constrained by topography than the deeper core and has velocity contours influencing depths down to ~2500 m.

3. Material and Methods

We report data from sediment cores recovered from sites located either side of the present-day boundary between LNADW and LSW, and above the primary fast

| Table 1. Limits and Characteristics of the Climatically Important Water Masses Within the DWBC* |
|---|---|---|---|
| Water Mass | Potential Temperature Range | Approximate Potential Density Range, kg m\(^{-3}\) | Approximate Depth, m |
| SLSW | 6°C > \(\theta\) ≥ 4°C | 41.00 < \(\sigma_3\) ≤ 41.27 | 1000–1800 |
| LSW | 4°C > \(\theta\) ≥ 2.8°C | 41.27 < \(\sigma_3\) ≤ 41.44 | 1400–2800 |
| LNADW | 2.8°C > \(\theta\) ≥ 1.9°C | 41.44 < \(\sigma_3\) ≤ 41.55 | 2500–4100 |
| BW | 6°C > \(\theta\) ≥ 4°C | \(\sigma_3\) < 41.55 | 3400 to bottom |

flowing core of the DWBC but below the shallower secondary core. The investigation of MIS 5 and the 5/4 transition utilizes cores from Sites 1057 and 1059 of the Ocean Drilling Program (ODP) Leg 172. Site 1059 (31°40.5′N, 75°25.1′W; Figure 1) is located at a water depth of 2985 m on a small sediment drift superimposed on the BOR [Keigwin et al., 1998; Keigwin and Schlegel, 2002] and the shallower Site 1057 (32°01.8′N, 76°04.8′W; Figure 1) is at 2584 m water depth. In addition, we use sediments recovered from R/V Knorr cruise KNR 140/2, the site survey cruise for Leg 172 [Keigwin, 2004], to study the Holocene at corresponding water depths to Sites 1059 and 1057. The deeper of the sites is 39GGC (31°40.1′N, 75°24.9′W; Figure 1) at a water depth of 2975 m, while 43GGC (32°01.0′N, 76°04.0′W; Figure 1) is situated at 2590 m water depth. Sediments from Site 1059 and core 39GGC are located within LNADW at a depth that is highly sensitive to changes in the composition of this water mass and particularly the degree of mixing with waters of southern origin from below. Site 1057 and core 43GGC are located in LSW, but close to the boundary between LSW and LNADW and are therefore ideally positioned to record changes in the relative influence of LSW and LNADW.

[9] Stable isotope records based on the benthic foraminifera Cibicidoides wuellerstorfi for Site 1059 during the 145–65 kyr interval (27.96 and 39.12 meters composite depth (mcd), average sample resolution of 5 cm) were previously published by Oppo et al. [2001] and Heusser and Oppo [2003], while benthic δ13C data for core 39GGC (Cibicidoides spp.) are taken from Keigwin and Schlegel [2002]. Planktonic δ18O records for cores 39GGC and 43GGC are from Keigwin [2004] and based on Globigerinoides ruber (white variety). In addition, Site 1057 was sampled every 5 cm between 11.48 and 13.98 mcd. We present new planktonic and benthic stable isotope data for Site 1057 determined on G. ruber and C. wuellerstorfi at Woods Hole Oceanographic Institute (WHOI) using a Finnigan MAT252 and calibrated to Vienna Pee Dee Belemnite (VPDB) following standard procedures [Keigwin and Boyle, 1999]. The long-term analytical precision based on over 2000 analysis of NBS-19 is ±0.07‰ for the δ18O data and ±0.03‰ for the δ13C measurements [Ostermann and Curry, 2000]. Unfortunately, benthic δ13C data could not be obtained from core 43GGC because of the absence of suitable benthic foraminifera.

[10] Samples for sedimentological analyses were disaggregated in pure water on a rotating carousel for 24 hours before being washed over a 63 μm screen to separate the “coarse” and “fine” fractions. The residues were dried at 50°C and weight percentage of the <63 μm and >63 μm fractions was determined by weighing.

[11] The biogenic calcium carbonate (% wt) contents for Sites 1059 and 1057 and cores 39GGC and 43GGC were indirectly estimated using a Carlo Erba EA1106 elemental CHN analyzer to measure the inorganic carbon content. All SS grain size measurements were undertaken using a Coulter Multisizer III following the methods described by Bianchi et al. [1999]. Measurements were made on the <63 μm terrigenous fraction following the removal of the biogenic carbonate by slow digestion in 1M acetic acid solution. Generally, the samples used in this study have an SS abundance of 8–10% enabling the determination of the SS with an error of 2.1% and 0.3% respectively [Bianchi et al., 1999]. The SS values obtained from analysis on the Coulter Counter cannot be directly compared with previous paleocurrent studies for MIS 5e based on Sedigraph measurements [e.g., Bianchi et al., 2001] as these two techniques use different principles to calculate the SS. The Coulter Counter measures the volume-equivalent spherical diameter inferred from electrical conductivity, while the Sedigraph provides a velocity-equivalent spherical diameter based on the settling principle (Stokes Law and assuming quartz densities) inferred from an X-ray scanning settling tube [McCave and Hall, 2006].

4. Chronology

[12] The benthic and planktonic δ18O stratigraphy for Sites 1059 and 1057 are shown in Figure 2. The temporal framework for Site 1059 is based on the previously published age model of Heusser and Oppo [2003], in which the benthic δ18O record was correlated to the chronology of Martinson et al. [1987]. This core provides the reference age model for all the other cores utilized in this study during MIS 5 and 4. The age model for Site 1057 was generated by graphic correlation to the chronology of Heusser and Oppo [2003] (Figure 2). Initially, the benthic δ18O isoropes were used to broadly correlate the two records (Figure 2a) and then the higher-resolution planktonic δ18O isoropes were used to fine tune the correlation (Figure 2b). Correlation between the planktonic δ18O records was mainly focused during the youngest part of the record between 65–75 kyr B.P. where the benthic δ18O record experiences some correlation difficulties. A notable period of light benthic δ18O values between 74 and 68 kyr in Site 1057 is difficult to reconcile with Site 1059 as can be observed in Figure 3c. However, there is a close similarity between the planktonic δ18O records during this interval allowing some confidence in our age assignment.

[13] A number of previously published records are introduced for comparison in section 5. In order to place each of these previously published records on a common timescale we have adjusted their chronologies to that of Site 1059 [Heusser and Oppo, 2003]. The age models of Site 1060 [Bianchi et al., 2001] at the BOR and KNR31-GPC-9 [Keigwin et al., 1994] on the Bahama Outer Ridge (BahOR) were adjusted via correlation of their benthic δ18O records with Site 1059. Core MD95-2036 [Lehman et al., 2002] at the Bermuda Rise was also modified on the basis of a correlation between its benthic δ18O record [Adkins et al., 1997; Lehman et al., 2002] and that of Site 1059, followed by fine tuning the MD95-2036 alkenone-derived sea surface temperature (SST) record and the planktonic δ18O record from Site 1059. The locations of the age control points and resulting sedimentation rates for each of the records are shown in the auxiliary materials.1

1Auxiliary materials are available in the HTML. doi:10.1029/2006PA001409.
while a tentative age model for core 43GGC was developed using two previously unpublished AMS dates located at 35 and 67 cm core depth. Although a lack of benthic foraminifera prevent correlation of the benthic oxygen records and the lower sedimentation rates (\( \sim 5.9 \text{ cm kyr}^{-1} \)) at Site 43GGC make the age model more ambiguous, it does not have a substantial effect on the broader relationship between the SS at 43GGC and 39GGC. All AMS dates were converted into calendar age using CALIB v.5.0 (M. P. Stuiver et al., CALIB 5.0, available at http://radiocarbon. pa.qub.ac.uk/calib/, 2005), assuming a reservoir correction of 400 years. Ages between age control points were estimated by linear interpolation.

**Figure 2.** Chronology for Sites 1059 and 1057. (a) Benthic \( \delta^{18} \text{O} \) data versus age (kyr B.P.). (b) Planktonic \( \delta^{18} \text{O} \) data versus age (kyr B.P.) for Sites 1059 (2997 m water depth) and 1057 (2595 m water depth). (c) Sedimentation rates (cm kyr \(^{-1}\)) for Site 1059. (d) Sedimentation rates (cm kyr \(^{-1}\)) for Site 1057. (e) Age-depth relationship for Site 1057. Site 1059 chronology is based on Heusser and Oppo [2003]. The age model for Site 1057 was generated by graphic correlation of the benthic and planktonic \( \delta^{18} \text{O} \) with the Site 1059 records. Solid lines show the correlation points used.
Figure 3. Holocene and MIS 5/4 proxy data for Sites 1059 and 1057. Note axis break between 10 and 60 kyr B.P. (top to bottom) (a) NGRIP $\delta^{18}O$ [North Greenland Ice Core Project Members, 2004], (b) CaCO3%, (c) planktonic $\delta^{18}O$ derived from G. ruber at both sites, (d) benthic $\delta^{18}O$ where based on C. wuellerstorfi from Site 1059 and Cibicidoides spp. at Site 1057, (e) SS (note reversed axis), and (f) benthic $\delta^{13}C$ versus age (kyr B.P.). See section 5 for a description of the data origin. Records from Site 43GGC/1057 (2590/2595 m water depth) are shown in red and from Site 39GGC/1059 (2975/2985 m water depth) are shown in blue. Warm interglacial/substages are shown in yellow. Vertical dashed lines refer to previously identified cold events (labeled) [Oppo et al., 2001; Heusser and Oppo, 2003].
At each location peak sedimentation rates typically occur during cold intervals while warmer intervals have reduced sedimentation rates. This is consistent with previous observations of low Holocene sedimentation rates at the North American continental margin [Keigwin and Jones, 1989; Haskell et al., 1991] and previous studies during the last interglacial [Bianchi et al., 2001]. The deeper sites, 1059 and 39GGC, record consistently higher sedimentation rates than the shallower sites because of the unusually high deposition rates that have led to the development of a sedimentary wave superimposed on the main sedimentary drift [Keigwin and Schlegel, 2002].

5. Results and Discussion

Numerous previous studies of the DWBC have made use of the grain size of the detrital silt fraction of cores from the crest of the BOR in order to study paleocurrent intensity [Johnson et al., 1988; Haskell et al., 1991; Haskell and Johnson, 1993; Bianchi et al., 2001; Yokokawa and Franz, 2002]. Here we use the SS grain size proxy, which provides an estimate of relative changes in near-bottom flow intensity of the depositing paleocurrent [McCave et al., 1995; McCave and Hall, 2006], with near-bottom flow speeds decreasing with distance from the fast flowing core of the DWBC [Stahr and Sanford, 1999].

The SS proxy can be used where the source sediment is characterized by a broad range of grain sizes and the distance to the core site is sufficient for a sorted signal to develop [McCave et al., 1995; Bianchi et al., 2001; McCave and Hall, 2006]. These conditions are met on the BOR as its supply of terrigenous sediment is principally transported by the DWBC [Heezen et al., 1966] from the American continental margin. Bianchi et al. [2001] confirmed that at Sites 1060 and 1062 on the BOR there was no significant sediment input from ice rafted debris (IRD) or turbidity current influence during the MIS 5 interval. Likewise, visual inspection and core logs from Sites 1059 and 1057, which are both located on the ridge crest and so less likely to be affected by turbidites and debris flows, show no evidence of any major down-slope deposition events.

It has been shown that the DWBC changed position and migrated vertically in the water column during past climatic cycles [e.g., Ledbetter and Balsam, 1985; Johnson et al., 1988; Haskell et al., 1991; Bianchi et al., 2001]. As pointed out by Bianchi et al. [2001], at any given point in time, no single value of the SS along the BOR is representative of the overall relative flow velocity of the DWBC. Therefore any sedimentological paleocurrent data from the BOR must be viewed in terms of both changing vigor at one or more given localities and position/depth of the DWBC. The records in this investigation (Figure 3) are interpreted using the same principles outlined by Bianchi et al. [2001], making the assumption that production rates of LNADW are a major control on the vertical movement of the DWBC. Therefore, as each of the core sites is located at water depths above the present-day fast flowing primary DWBC core, a synchronous increase in SS at both depths is indicative of a shoaling of the DWBC core and a reduction in LNADW production.

5.1. Paleocurrent Variability During the Holocene

Recent studies have suggested that the modern hydrographic regime in the western North Atlantic may have only been established ~7 kyr B.P. when the formation of LSW started [Hillaire-Marcel et al., 2001; Cottet-Puinel et al., 2004]. The Holocene records of cores 39GGC and 43GGC younger than ~7 kyr should therefore be most akin to the present-day hydrographic setting at the BOR and these data offer us the chance to “ground truth” the configuration of proxy data, employed for the MIS 5 interval, to the modern setting.

The SS record for core 39GGC is suggestive of a variable DWBC throughout the Holocene (Figure 3e). Benthic δ13C data from core 39GGC suggest decreased ventilation of LNADW after ~8 kyr B.P. consistent with previous studies [Oppo and Fairbanks, 1987; Boyle and Keigwin, 1987]. This, in conjunction with the SS data, implies greatest relative LNADW flow occurred early in the Holocene. However, the most important conclusion for this study is that the lower-resolution SS record from core 43GGC displays broadly similar values to those recorded at the deeper core 39GGC. This most likely indicates the continuous presence of an active shallow limb of the DWBC, as detailed by modern hydrographic studies [Johns et al., 1997; Stahr and Sanford, 1999] in the area, elevating the SS grain size at core 43GGC. A lack of benthic δ13C data prevents the geochemical assessment of changes in ventilation at this site.

5.2. Paleocurrent Variability During MIS 5 and 4

The boundaries of the MIS 5 substages [Shackleton, 1969] discussed in this study are defined according to those set out by Heusser and Oppo [2003] and are represented by areas in yellow in Figure 3. Comparing the SS for Sites 1057 and 1059 across the entire MIS 5 interval and into MIS 4 reveals the changing relationship of the relative flow speeds recorded at each site. Site 1057 shows a slight increasing trend in the SS throughout the record, a trend that is not present at Site 1059, although the SS increases in unison at both sites during the latter part of cold substages 5d, 5b and during early stage 4 in conjunction with previously identified marine cold events (e.g., C19, C20, C21 and C23 [McManus et al., 1994; Oppo et al., 2001; Heusser and Oppo, 2003]). The δ13C variations at Site 1057 also show a general increase to heavier values throughout the record, intersected by lighter excursions, indicating declining or reduced deep ocean ventilation during the larger cold events (C19–C24). Site 1059 records more pronounced excursions during these cold episodes, but the δ13C values during the warm substages (5c and 5a) remain similar to MIS 5e values.

During MIS 5e and early 5d (Figure 3e), the shallower Site 1057 records lower SS grain size values (mean = 15.4 μm) than Site 1059 (mean = 17.1 μm) and these are the lowest SS values throughout the record and are also lower than those observed in core 43GGC during the Holocene. The SS offset between the two sites is reasonably constant (1.7 μm ± 0.75 μm) and this observation strongly corroborates one of the key assumptions in this work that sedimentation in the sortable silt range on the crest of the
BOR is predominantly controlled by deepwater currents rather than simple down slope sediment movement where coarser grain sizes would always be found at shallower depths [Haskell et al., 1991; Haskell and Johnson, 1993]. Throughout the MIS 5e interval the benthic $\delta^{13}C$ (Figure 3e) at both sites are similar at around 0.7% and imply the presence of a well mixed water mass between the sites. To further investigate the extent of this water mass, benthic $\delta^{13}C$ data were incorporated from two deeper sites (Figure 4), ODP Site 1060 on the BOR (3480 m water depth [Bianchi et al., 2001]) and core GPC-9 on the BahOR (4758 m water depth). Data for Site 1060 are from Bianchi et al. [2001] and are based on Cibicidoides wuellerstorfi, Cibicidoides spp., and Uvigerina spp. The $\delta^{18}O$ results for C. wuellerstorfi and Cibicidoides spp. have been corrected by +0.64% to account for species-dependent isotopic fractionation, and a correction of +0.7% has been applied to the $\delta^{13}C$ data for Uvigerina spp. (see Bianchi et al. [2001] for further details). The GPC-9 data from Keigwin et al. [1994] only show the Cibicidoides spp. record in this study. Warm interglacial/substages are shown in yellow. Vertical dashed lines refer to previously identified cold events (labeled) [Oppo et al., 2001; Heusser and Oppo, 2003].

Figure 4. Extended depth range benthic isotope ($\delta^{18}O$ and $\delta^{13}C$) and CaCO$_3$ (wt %) data. (top to bottom) (a) Benthic $\delta^{18}O$, (b) benthic $\delta^{13}C$, and (c) CaCO$_3$ versus age (kyr B.P.). Records are shown in red (Site 1057, 2584 m water depth), blue (Site 1059, 2985 m water depth), black (Site 1060, 3480 m water depth), and green (GPC-9, 4758 m water depth). Data for Site 1060 are from Bianchi et al. [2001] and are based on Cibicidoides wuellerstorfi, Cibicidoides spp., and Uvigerina spp. The $\delta^{18}O$ results for C. wuellerstorfi and Cibicidoides spp. have been corrected by +0.64% to account for species-dependent isotopic fractionation, and a correction of +0.7% has been applied to the $\delta^{13}C$ data for Uvigerina spp. (see Bianchi et al. [2001] for further details). The GPC-9 data from Keigwin et al. [1994] only show the Cibicidoides spp. record in this study. Warm interglacial/substages are shown in yellow. Vertical dashed lines refer to previously identified cold events (labeled) [Oppo et al., 2001; Heusser and Oppo, 2003].

The benthic $\delta^{13}C$ records during MIS 5e are indicative of a water column that is dominated by northern source waters (NSW). However, the benthic $\delta^{13}C$ signature is slightly lighter than that experienced by core 39GGC in the Holocene (Figure 3f) and the $\delta^{13}C$ of ~1‰ [Kroopnick, 1985; Curry and Oppo, 2005] associated with contemporary LnadW. This suggests poorer ventilation during MIS 5e than the Holocene, with $\delta^{13}C$ values similar to those expected for the present-day BW of Stahr and Sanford [1999, section 1.2] where the influence of AABW is believed to slightly decrease the benthic $\delta^{13}C$ signature [Keigwin et al., 1994]. Today, BW on the BOR is restricted to water depths below 3400 m and only contributes about 15% to the overall transport [Stahr and Sanford, 1999]. However, it is suggested that during peak MIS 5e a NSW mass with a similar benthic $\delta^{13}C$ value to present-day BW extended throughout the water column, at least up to ~2600 m water depth, at the BOR.

The clear offset between the SS of Sites 1057 and 1059 demonstrates that flow conditions of the DWBC were also considerably different compared to the Holocene (Figure 3e). The SS record at Site 1059 suggests an
approximately stable position for the axis of the deeper DWBC limb below at least 2985 m water depth, consistent with the paleocurrent reconstruction of Bianchi et al. [2001] who suggested that during MIS 5e the DWBC was located below Site 1060 (3461 m water depth). These latter data are based on Sedigraph analysis of the SS component and the resulting grain sizes are therefore not directly comparable with the SS estimates presented in this study.

[25] The lower SS recorded at Site 1057 is suggestive of a weakened LSW production, which would have presumably caused a shoaling or possibly even a loss of the upper dynamic limb of the DWBC, which is LSW-sourced at these depths today. In the absence of any significant influence from the shallower DWBC core Site 1057 would be distant and isolated from the deeper fast flowing core of the DWBC. The formation and properties of the North Atlantic intermediate and deep water over the last interglaciation are contentious. Hillaire-Marcel et al. [2001] suggest that LSW formation was absent during the last interglacial and advocate the presence of a single water mass originating from the Nordic Seas overlain by a thin buoyant surface layer. While Rasmussen et al. [2003] conclude that LSW, with a fairly similar composition as today, was generated throughout the peak of MIS 5e. They also suggest the presence of a benthic foraminiferal “Atlantic assemblage” that does not appear to be linked to overflow water from the Nordic Seas. The compiled benthic $\delta^{13}$C record presented here strongly support the presence of a uniform water mass, dominated by LNADW below ~2500 m on the BOR, during peak MIS 5e, with evidence from the Site 1057 flow speed record of a weakened LSW. At 2584 m water depth Site 1057 is located at the base of LSW influence on the BOR and therefore highly sensitive to relative changes in LSW and LNADW production and DWBC flow. However, we need to be cautious as, clearly, on the basis of our SS data alone we cannot rule out continued vigorous production of SLSW ventilating shallower depths.

[26] The benthic $\delta^{13}$C records (Figure 4b) suggest an apparent reorganization in the hydrography and flow of the DWBC starting close to the MIS 5e–5d boundary at ~117–110 kyr B.P. At this time a significant lowering of $\delta^{13}$C values was experienced at the two deeper sites (Sites 1060 and GPC-9) indicative of decreasing ventilation, while conditions at the two shallower sites (1057 and 1059) experience a smaller shift toward heavier values. In terms of the SS records this transition is much more obvious but is marked by the onset of gradually increasing SS at Site 1059 and 1057 (Figure 3e). These data support a shoaling of the water column structure in response to a decrease in LNADW production at that time [Adkins et al., 1997; Hall et al., 1998]. Such a transition is consistent with the indication of a reduction in the depth of the deep core of the DWBC suggested in the Site 1060 SS record at ~118–117 kyr [Bianchi et al. 2001]. Bianchi et al. [2001] suggest that it was only after ~113 kyr that the core of the DWBC shoaled above Site 1060. This study further suggests that the reduced LNADW between ~118–113 kyr is part of a longer transition. At ~111 kyr B.P., a significant shift in the relationship between the SS and benthic $\delta^{13}$C is observed at Sites 1057 and 1059 (Figures 3e and 3f); a SS increase at Site 1057 is responsible for the flow speed records at both sites converging and subsequently behaving more coherently through the remainder of MIS 5 and into MIS 4. We suggest that such behavior is indicative of the reestablishment of a stronger and possibly deeper secondary core of the DWBC after ~111 kyr. The strengthening and deepening of the shallower core would increase the flow speeds recorded at Site 1057 while possibly depressing the depth of the deeper flowing DWBC core. Coincident with this shift, the benthic $\delta^{13}$C records diverge and Site 1057 benthic $\delta^{13}$C values increase to typically >1‰ while the long-term values at Site 1059 remain unchanged. Immediately following this divergence the benthic $\delta^{13}$C at GPC-9 reach minimum values (Figure 4b). The increased benthic $\delta^{13}$C values at Site 1057 imply the development of a clear hydrographic boundary in the ~500 m of water column that separate the two sites. The shallower, more nutrient depleted water mass has benthic $\delta^{13}$C values slightly higher than those experienced in the Holocene at 39GGC, implying that this water mass is of a northern origin and may represent the initiation of, or a similar water mass to Glacial North Atlantic Intermediate Water (GNAIW) formation. This is supported by Chapman and Shackleton [1998, 1999] and Chapman et al. [2000] who suggest that the gradual increase in $\delta^{13}$C values in core SU90-03 (40°N, 32°W, 2475 m water depth) in the North Atlantic during MIS 5, could signify a long-term change in the depth and/or production rate of NADW. This, in conjunction with the reestablishment of the shallower core of the DWBC, could also explain the long-term increase in the SS evident at Site 1057 throughout the record (Figure 3e). However, it should be noted that Oppo and Lehman [1995] documented a similar rising trend in benthic $\delta^{13}$C within MIS 5 in subpolar North Atlantic core V29-202 (2658 m water depth), and argued that it was driven by the changing composition of tropical surface feed waters, driven by either biological or thermodynamic processes. However, our grain size records demonstrates that a change in DWBC geometry occurred over MIS 5 and suggests that observed benthic $\delta^{13}$C values cannot be explained solely by changes in the preformed composition of the surface waters, but must involve a physical change in deep ocean circulation.

[27] Curry and Oppo [2005] demonstrate that the sharp boundary at ~2 km in the subpolar North Atlantic between northern and southern source water masses during the LGM is eroded as GNAIW flows southward toward the BOR study sites and mixes with Southern Ocean waters. At comparable latitudes to the BOR the whole depth range from 2–4 km appear to be in a mixing zone. Although the precise geometry described by Curry and Oppo [2005] during the LGM may differ slightly from that experienced within MIS 5 our results suggest that once the $\delta^{13}$C gradient was established it persisted throughout the subsequent glaciation and that at least 1059 lay in a water mass gradient most of the time. This is supported by data from GPC-9 [Keigwin et al., 1994, Figure 6c], which show a similar benthic $\delta^{13}$C pattern to the shallower two sites but with a more pronounced influence of AABW.

[28] The latter parts of cold substage 5b and, to a lesser extent, 5d are characterized by a transient interval of
increased SS associated with significant positive excursions in the planktonic δ¹⁸O records at each site indicative of sea surface cooling (cold events: C24, C23 and C21; see section 5.3; Figures 3c and 3e). A lack of benthic foraminifera, possibly due to the increased influence of corrosive southern-sourced AABW, particularly during the MIS 5b event, precludes a clear observation of the hydrographic changes associated with these intervals but do hint at reduced water column ventilation. An increase in dissolution during these intervals is consistent with the reduced CaCO₃ observed (Figure 4c). The maxima in DWBC flow speeds during these intervals are indicative of a rapid shoaling of the DWBC to a depth at which the fast flowing core is close to Sites 1059 and 1057 and most likely increased influence of AABW.

[30] MIS 4 is only partly represented in our records. However, it is during this interval that the largest changes in DWBC flow speed and hydrography are recorded. Two δ¹³C excursions centered at ~75 and ~69 kyr, consistent with surface cooling events C20 and C19, are associated with a substantial increase in the flow speed at Site 1057 and a smaller increase at the deeper Site 1059 (Figures 3c and 3e). This suggests a significant decrease in NADW/GNAIW production leading to a rapid shoaling of the deeper DWBC core more proximal to and possibly above Site 1057. These flow speed changes are accompanied by similarly abrupt excursions in the benthic δ¹³C records at both sites, and have also been previously documented on the BahOR [Keigwin et al., 1994]. In the case of the younger C19 event benthic δ¹³C values fall to below −0.5‰ at both Site 1057 and 1059, characteristic of a water mass similar to unmodified AABW during the LGM [Oppo and Fairbanks, 1987; Curry et al., 1988]. During the interstadial intervals surrounding these cold events the benthic δ¹³C and SS values return to similar levels as those observed during MIS 5a. The correlation of these events in the deep ocean to other proxies such as the δ¹⁸O NGRIP record which provides a temperature proxy record for the northern North Atlantic (Figure 3) highlights the potential global significance of these oscillations.

5.3. Surface–Deep Ocean Links

[30] Oppo et al. [2001] have previously made a detailed study comparing the planktonic δ¹⁸O record at Site 1059 to its benthic δ¹³C record, finding virtually synchronous oscillations between the two proxies suggestive of a persistent surface-deepwater linkage from early in MIS 5e. Oppo et al. [2001] argue that SST variability provides the simplest explanation for the suborbital oscillations (4–10 kyr pacing) in planktonic δ¹⁸O apparent during MIS 5, as they are similar in magnitude and timing to the planktonic δ¹³O variations in MIS 3, which have been previously attributed to SST [Keigwin and Boyle, 1999; Sachs and Lehman, 1999]. In this study it is clear that planktonic δ¹³O [Oppo et al., 2001] evidence for surface cooling, particularly during cold events C24–C19, is not only associated with weak NADW (low benthic δ¹³C), but also corresponds to a shoaling DWBC as represented by increasing SS values (Figure 3).

[31] No specific SST proxy measurements are available for MIS 5 from the BOR, so in Figure 5 we compare the Site 1057 and 1059 proxy records with the high-resolution SST record derived from measurements of the unsaturated alkenone ratio in core MD95-2036 recovered from the nearby Bermuda Rise (33°41.444'N, 57°34.548'W, 4462 m water depth [Lehman et al., 2002]). The correlation between the SST at MD95-2036 and the planktonic δ¹³O at Sites 1057 and 1059 (Figure 5a) confirms the presence of a series of synchronous abrupt cooling events at each site. Intriguingly, comparison of the alkene-derived SST record and the planktonic δ¹³O record of Site 1059 also reveals a lack of shorter-timescale structures in the alkenone record compared to the planktonic δ¹³O record. This finer structure in the Site 1059 planktonic δ¹³O data could be a function of changes in sea surface salinity (SSS), which is not recorded in the purely temperature-related alkenone record. Alternatively, the finer-timescale structure may be lost in the alkenone record because of mixing of alkenones of different ages in any one sample [Ohkouchi et al., 2002], or it could result from changes in seasonality, preservation or depth habitat between the two proxies [e.g., Popp et al., 2006].

[32] Lehman et al. [2002] showed a strong correlation between their alkenone record and the benthic δ¹³C data of GPC-9 on the BahOR [Keigwin et al., 1994]. They observed a clear correspondence between low SST and low δ¹³C values, which is also recorded in the SS record of Hall et al. [1998] in MD95-2036, as evidence of reduced NADW formation. This has resulted in speculation that local suppression of deepwater formation is one likely mechanism for the amplification of the direct cooling effects of iceberg melting and ice sheet discharge [Lehman et al., 2002]. The relationship described by Lehman et al. [2002] together with the findings of Oppo et al. [2001] are further substantiated by the benthic δ¹³C record of Site 1059 that shows a strong relationship between colder SSTs and low benthic δ¹³C (Figure 5c), suggesting reduced LNADW formation during cold intervals with a greater influence of AABW. During MIS 5 and the 5/4 transition, this relationship is less pronounced at the shallower Site 1057 probably in part because of the lower resolution and the proximity of GNAIW that maintains high δ¹³C values. Comparison of the MD95-2036 alkenone SST record, the Site 1059 planktonic δ¹³O record and Site 1059 SS (Figure 5b) reveals a striking and persistent relationship throughout MIS 5 and the 5/4 transition. This suggests a very tight linkage between SST in the subtropical western North Atlantic and DWBC activity which extends north to the Bermuda Rise. The link between these shallow and deep locations may lie in the Nordic Seas. During the last glacial surface temperature variations in the Nordic Seas coincided with deepwater changes [Fronval and Jansen, 1996; Fronval et al., 1998], with the majority of fluctuations being related to reductions in the AMOC. Furthermore, Oppo et al. [2001] suggest that during deglacial and glacial periods ocean-ice interactions and deepwater variability may amplify suborbital variability. They suggest that during the penultimate deglaciation NADW production varied between the Nordic Seas and open North Atlantic positions, similar to the situation thought to occur during the LGM [Boyle and Keigwin, 1987], and this occurred in parallel with SST oscillations. It is suggested that this situation was
not confined to the penultimate deglaciation but played an important role throughout MIS 5 and into MIS 4, with warm water penetrating into the Nordic Seas resulting in melting of ice and a weakening of NADW formation [Oppo et al., 2001]. The effects of these intervals of weaker and shallower NADW formation are not confined to the marine environment. They can also be linked to cold events in the terrestrial pollen record of the southeastern United States [see Heusser and Oppo, 2003] and the larger oscillations (C19–C24) have cold counterparts in the Greenland Ice core records (Figure 3). Although the cause of such suborbital variability remains unknown, the observed variations in deepwater circulation and the associated northward transport of heat are likely to have played an important role communicating the climatic variation throughout the wider circum-North Atlantic region [Heusser and Oppo, 2003].

6. Summary and Conclusions

This study presents the first comprehensive SS records and δ13C gradients between sites on multiple cores for MIS 5 and early MIS 4. A schematic representation of the water column and high-velocity core of the DWBC on the eastern flank of the BOR during the major intervals discussed above is presented in Figure 6. Paleocurrent and hydrographic reconstructions suggest that the configuration of DWBC flow was substantially different during peak MIS 5e from the Holocene with strong evidence for a weakened LSW influence. Instead, a well mixed water
mass, dominated by LNADW but less well ventilated than during the Holocene was present over a broad depth range from 2584 m to 4758 m water depth. We show that the MIS 5e configuration was terminated by a significant shift in DWBC flow characteristics coincident with a hydrographic change that began as early as /C24 118–117 kyr culminating in the transition midway through MIS 5d. It appears this shift may represent the initiation of GNAIW formation, with Sites 1057 and 1059 lying in the gradient between nutrient depleted GNAIW and nutrient enriched AABW for the remainder of MIS 5 confirming that the Atlantic was stratified during MIS 5d–5a [Chapman and Shackleton, 1998, 1999]. Large correlative suborbital oscillations during the latter part of the cold substages MIS 5d and 5b, as well as early MIS 4 can be correlated to the surface cooling events of McManus et al. [1994], and imply a rapid shoaling of the DWBC high-velocity core and incursions of AABW to shallower depths. Such data demonstrate that the δ^{13}C variations suggested to be related to abrupt deepwater hydrographic variations are also associated with large-scale dynamic changes in the DWBC flow. Furthermore, comparison with surface ocean oxygen isotope records and the alkenone-derived SST estimates for core MD95-2036 on the Bermuda Rise [Lehman et al., 2002] highlight a persistent link between subtropical North Atlantic surface ocean climate and the dynamics of the underlying DWBC. The results of this study demonstrate the importance of using multiple proxies related to both the hydrographic properties of deep ocean water masses and

Figure 6. Schematic representations of the high-velocity core of the DWBC on the eastern flank of the BOR. (a) Present day [after Stahr and Sanford, 1999]. (b) Peak MIS 5e. The influence of LSW and the shallow core have been reduced. The main axis of the current remains close to its present position but with the presence of a well-mixed water mass. (c) MIS 5 after ~111 kyr B.P., with the reintiation of the shallower secondary core of the DWBC. LNADW has been replaced by a GNAIW-like water mass. The sites sit in the gradient between these water masses. (d) Marine cold events C19, C20, C21, and C23 showing an incursion of AABW to shallower depths and a shoaling of the high-velocity core of the DWBC proximal to Sites 1059 and 1057. The boundaries of the various water masses defined within the text are shown by dashed lines along with the depths not the positions of the sites under investigation. Arrows indicate the fluctuating behavior of the water mass boundaries. The position of these idealized cross sections is shown in Figure 1.
dynamical tracers of deep ocean flow in order to provide a better appreciation of past AMOC variability.
