#### Abstract

In this work a large collection of VLBI (Very Long Baseline Interferometry) maps are presented based upon data from the VLBA (Very Long Baseline Array) for 29 sources. The maps are the result of three epochs of imaging. A kinematic study was undertaken with a view to understanding some interesting structure seen in the quasars 3C273 and 3C345. Fortunately, these two sources present a large number of components and it was possible to perform model fitting to pinpoint their positions. In addition, model fitting was performed upon all of the sources that were successfully imaged. The aim of this was to eventually derive component velocities for as many blazars studied as possible. The outcomes of the work are presented in tables in the main thesis. In order to further understand the 3C273 and 3C345 jet structures seen a physical model was developed with A. Papageorgiou. With this kinematic model it was possible to trace out a variety of helical jet structures. The free parameters are the injection velocity for new components, the period of jet precession, the viewing angle and the jet half angle. Using the LevenbergMarquardt algorithm (references given below) it was possible to fit jet trajectories to my model fitted component data. The algorithm produced quantitative output for some of the free parameters in my physical model. Therefore I report average jet half angles for 3 C 273 and 3C345 of $2.968 \pm 0.153$ degrees and $2.519 \pm 0.573$ degrees respectively. In addition, I find the precessional periods of 3C273 and 3C345 to be $71.161 \pm 19.066$ years and $48.478 \pm 3.385$ years respectively.

## Acknowledgments

...you know that when your faith succeeds in facing such trials, the result is the ability to endure. (James 1:3)

I would like to begin by thanking those closest to me for their constant love and support. I would like to acknowledge my parents for always being at the other end of the phone to lend their encouragement and understanding. Diolch yn fawr iawn to Llinos for suffering my many research frustrations. You are such a positive person with the brightest of personalities. (I can't wait for the 23rd of July!) Your love and belief in me has kept me going to reach this place. All three of you were such an important and real component of what I have achieved and I dedicate this thesis to you.

Thanks to my family and friends who have not been mentioned so far. I do appreciate their trying to understand what my PhD was all about!

A huge thank you to my future best man Dave Cunnah. Those lunch time breaks really helped to maintain my sanity at times! Also your advice and input with regard to my curve fitting work was a huge help and I would have been struggling without it. Thank you for your time and effort. I really do value and enjoy our friendship.

I must say a huge thank you to Andreas Papageorgiou for playing a massive role in what I have managed to do. His guidance on the dark and forbidding world of VLBI map making was invaluable to me. I would also like to thank him for his contribution to the helical jet model that we developed together. His ability to point me in the right direction was a key element in deriving an interesting model to use in my work. Finally, I would
like to say thank you to Andreas for his patience and time. I can remember feeling rather guilty at times over how many questions I had to ask you!
I would like to thank Piers Horner for his kind help and advice. It was a pleasure to work with him and his knowledge of IDL was most valuable to me. I really do appreciate the time that he gave over to our discussions.

Finally, I would like to give my thanks to Walter Gear for his input and for giving me the opportunity to pursue a research project on AGN.

## Chapter 1

## Introduction

The work herein has focused on relativistic Blazar jets imaged on pc-scales. Astrophysical jets were discovered by Heber Curtis in 1917, who described M87's jet as a straight ray connected with the nucleus (McKinney and Blandford, 2009). Specifically, the source 3C273 was observed as a jet-like feature at radio wavelengths in 1963 (Kembhavi and Narlikar, 1999). Therefore, there has been much time to study blazar jets and VLBI has allowed high resolution (mas) imaging of such sources. Our limit is now the core, where the jets become optically thick and we can see no further. Unfortunately, this also limits our ability to understand what is occurring physically in the innermost parts of AGN systems. Indeed, one of the most interesting questions on blazar jets is how they are launched in the first place. It may be possible that the inner torus provides a funnel that collimates the jets in the first instance. Also, it may be the case that magnetic field lines that become twisted in the plasma present in the accretion disc become present in the jets as well. The wound up lines of magnetic field could accelerate and collimate the flow.

As a group, Blazars are composed of Quasars and BL Lac objects. Both of these subgroups can be described via the Unified Model of AGN. This model is best considered using a diagram. The conception of AGN unification in Figure 1.1 is an excellent visual picture, taken from http://crab0.astr.nthu.edu.tw/ hchang/ga2/f2703-unifiedmodel.JPG.

The sketches in Figure 1.2 also give an impression of the importance of viewing angle in the context of AGN unification.

The unified model provides a convenient conceptual picture of the principle workings of an AGN. But how have AGN been classified into different groups? There are two important divisions:

1. The division between objects with or without strong broad emission lines.
2. The division between sources which do or do not have strong radio emission and jets. This is the radio loud/ radio quiet division.

### 1.1 The Main Features of an AGN

Diagrams of the Unified Model such as Figure 1.1 help in showing broadly how the main features of AGN are situated. At the centre of the AGN lies a supermassive black hole ( $10^{6}$

Figure 1.1: A diagram of the Unified Model of AGN.
up to $10^{9}$ solar masses). This is sometimes thought of as the central engine of the AGN. An accretion disc surrounds the black hole and remains in place due to the immense gravity of the central engine. This accretion disc provides a 'fuel supply' for the AGN and jets, where plasma infalls towards the black hole. There is a torus of dusty material that exists around the accretion disc and black hole. The material therein has gravitational potential energy. To infall onto the accretion disc such matter must lose angular momentum. As it does so it is accelerated and heated to very high temperatures forming a plasma. This is the plasma that was previously mentioned with respect to the accretion disc. The accretion disc thus becomes very bright, contributing to the huge luminosity of the AGN.

It should be noted that material infalling towards the black hole is unlikely to be of uniform density. More dense regions of material will boost the luminosity of the accretion disc and less dense regions will lower it, although only temporarily (Freedman and Kaufmann III, 2002). This introduces the variability property of AGN.

One of the most prominent features of AGN is their variability. In some cases this can be quite rapid. For example, quasars can exhibit optical variability over timescales as long as years and as short as 15 minutes. It is known that optical variables show significant behaviour of this kind at radio wavelengths as well (Zeilik and Gregory, 1998).

It is thought that jets in blazars are launched by magnetic processes in plasma that is accreting onto black holes (Meier and Nakamura, 2006). Magnetic field structures are thought to exist in the accretion discs of AGN (due to the presence of plasma). It is thought that these structures become twisted near the black hole as the AGN system rotates around its centre of mass. It is thought that helical magnetic field lines then emerge perpendicular to the plane of the accretion disc. These are some of the most notable structures close to the site of jet launching.

Figure 1.2: Sketches of the main AGN types (sketches by the author, based on material in Cosmos by Giles Sparrow (Sparrow, 2006)).

### 1.2 Context

It is suitable at this early stage to ask where we might find Blazars in the Universe, both in terms of scale and distance.

Radio loud AGN are associated with elliptical galaxies whereas radio quiet AGN are found mostly in disks (Krolik, 1999). With VLBI, the cores of AGN may be resolved in pc-scale images of the jets. The accretion disc that surrounds the central black hole has a typical size of order $10^{-3} p c$. As an indication of their extent, the jets can be studied on kpc-scales.

In the sample of 29 sources that were analysed for this work, redshifts ranged from very much less than unity, up to around two.

### 1.3 Blazar Jets: A General Description

Of the various objects that the Standard Model of Active Galactic Nuclei (AGN) suggests, Blazars are the most powerful. Some of the brightest Blazars can reach fluxes of around $20 J y$. This scales down to roughly 100 mJy for the weakest observed sources. As a class of AGN, Blazars encompass Bl Lac objects and Highly Polarised Quasars (HPQs) and as such, are radio-loud as well as being compact. Rapid variability is observed over all wavelengths in timescales as short as days. In terms of the spectra of such sources, radio emission is seen to have a very flat profile. This then breaks into a steep spectrum in the millimetre through to the infrared range. The continuum emission from Blazars is significantly polarised.

### 1.4 Blazar Jets: Physical Mechanisms

At present (on pc-scales) the Shock-in-Jet Model (Marscher and Gear, 1985) is still considered by many to be the generally accepted standard of theoretical modeling. This model will be discussed in detail below. But first some rather more basic physical considerations.

Viewing Blazars along a line of sight by definition close to their relativistic jets, we observe synchrotron emission along with highly variable emission across all wavelengths. Blazar spectra are characteristic of synchrotron radiation, which by its nature is polarised. Synchrotron radiation can be defined in terms of a power law energy spectrum as follows:

$$
\begin{equation*}
N(E) d E \propto E^{-s} d E \tag{1.1}
\end{equation*}
$$

Where $N(E) d E$ is the number of electrons per unit volume at an energy $E$ and $s$ is the spectral index for the electron distribution.

In terms of a frequency spectrum for relativistic electrons, I shall take the convention that $\alpha$ (frequency spectral index) is positive, but implies a negative power law frequency spectrum (that is, $I(\nu) \propto \nu^{-\alpha}$ ) for AGN.

Electrons emitting synchrotron radiation lose energy at a rate given in the following expression:

$$
\begin{equation*}
-\frac{d E}{d t}=\frac{4}{3} \sigma_{T} c\left(\frac{E}{m_{e} c^{2}}\right)^{2} \frac{B^{2}}{2 \mu_{o}} \propto E^{2} B^{2} \tag{1.2}
\end{equation*}
$$

Where $\sigma_{T}=\frac{e^{4}}{6 \pi \epsilon_{c}^{2} c^{4} m^{2}}$ is the Thompson cross-section, the effective surface area of an electron with respect to a nearby photon.

A compact radio core is observed in the one-sided jets of Blazars (usually at their ends). When imaging with VLBI this is commonly referred to as the VLBI core. It is usually unresolved even by high frequency VLBI. In addition, radio components called knots are also observed. They are thought to be associated with periods of high activity within the central engine of the AGN. Knots are often seen to propagate down the jets at superluminal speeds, although some can be observed to be stationary. It is common to observe relativistic jets having bends in their structure, which could be associated with such knots in the jet flow.

### 1.4.1 The Nature of Components in Extragalactic Jets

Intense regions of emission that stand out in images of jets are a familiar phenomenon. As well as imaging of components with the VLBA for example, it is known that jet components' synchrotron self-absorbed spectra superpose to give an apparently flat overall spectrum in the radio to millimetre regimes. The spectrum falls off at infrared frequencies. Figure 1.3 shows how the overall spectrum would look. The arrow indicates spectra for individual components tending towards lower frequencies with time. This occurs as the components proceed down a jet flow.

Figure 1.3: Frequency Spectrum of Jet Components

The actual nature of components is still debatable. The components could be shocks. This means that components are the means by which electrons in the jets are reaccelerated. Alternatively, components could be intense regions of plasma injected into the jet flow from the core.

### 1.4.2 Shock Acceleration

Energetic particles may gain further energy by elastically scattering off magnetic structures within extragalactic jets (Rieger et al., 2007). Shocks will cause magnetic field lines to become more prominent along a direction perpendicular to the jet axis. ${ }^{1}$ Therefore magnetic structures that are predominantly perpendicular to the jet axis can be considered as originating from jet components.

Shock acceleration favours particles whose mean free paths are a) longer than the width of the shock and b) shorter than the length of fluid either side of the shock (Krolik, 1999). In this case, each time a particle crosses the shock it will be reflected back and will gain energy steadily.

The creation of shocks could be a result of an atypically large injection of relativistic electrons into a jet (Garcia, 1995).

### 1.4.3 The Three Stages of the Shock-in-Jet Model

There is an apparent paradox raised by the lengths of Blazar jets when the rate of energy loss by synchrotron radiation is considered. Without some form of additional acceleration of the electrons it is difficult to answer this paradox.
A possible solution is shocks. They are likely to exist in extremely fast flows (Reynolds, 2002) and they could propagate down the jet providing electron acceleration. This would prolong the lifetime of the electrons.

[^0]The shock-in-jet model allows us to concisely summarize the evolution of a typical flaring jet component into three epochs. Following the breakdown of this model given by Marscher and Gear (1985) a newly injected jet component will initially have the effect of boosting the flux density observed in the millimetre to infrared regimes. However this process is short-lived and the first phase of the shock-in-jet model begins almost instantaneously. In this phase, referred to by Marscher and Gear (1985) as the Compton stage, the initial flux density boost caused by the new component has the effect of increasing the photon energy density, $u_{p h}$ in the jet as described below:

$$
\begin{equation*}
u_{p h} \propto K\left(B^{3 s+7} R^{s+5}\right)^{\frac{1}{8}} \propto R^{-\frac{(13 s+17)+3 a(3 s+7)}{24}} \tag{1.3}
\end{equation*}
$$

Here $K=K_{0}\left(\frac{R_{0}}{R}\right)^{\frac{2(s+2)}{3}}$ and is a parameter of the electron energy distribution, $R$ is the distance from the vertex of the jet that is modelled as a cone, $a$ is the exponent of radial variation in magnetic field strength ${ }^{2}$ such that $B \propto R^{-a}$ and $s$ is as defined earlier. This leads to Inverse Compton processes dominating, imposing large energy losses on the electron distribution in the region. These losses are observed as a 'bump' of x-ray emission in the Blazar frequency spectrum. This boost in x-ray emission leads to an increase in flux density due to synchrotron losses as the jet component propagates down the jet. (Often, the resulting sequence of boosted emission in x-rays and then in the millimetre to infrared range is the first sign to extragalactic astronomers that a Blazar is in the process of flaring. Also, the x-ray flare will lag slightly behind the initial flare in flux density in the millimetre to infrared regimes that initiates the Compton stage.) This is thus termed the Synchrotron stage; the second of the three epochs in the shock-in-jet model. Beginning in the millimetre to infrared wavebands, this boost in synchrotron emission will shift down into lower frequencies (towards the radio waveband) with a fairly constant peak flux density, $S_{m}$ as the component evolves:

$$
\begin{equation*}
S_{m} \propto v_{m}^{\frac{(2 s-5)(2+3 a)}{4(s+2)+3 a(s-1)}} \propto R^{\frac{-8(s-1)-3 a(4 s-9)}{6(s+4)}} v^{\frac{-5}{2(s+4)}} \tag{1.4}
\end{equation*}
$$

$v_{m}$ above is the turnover frequency of synchrotron emission. In the final epoch, the adiabatic stage, the shock is seen to expand and decay such that its flux density, $S_{v}$ is modelled via the following equation:

$$
\begin{equation*}
S_{v} \propto R^{\frac{-7(s-1)}{6}} v^{\frac{-(s-1)}{2}} \tag{1.5}
\end{equation*}
$$

The energy of the shock decreases as the reciprocal of its separation from the core, until it is no longer resolved. Radiative processes appear to be no longer important during this final phase.

### 1.4.4 Doppler Beaming

The emission from Blazars is highly Doppler beamed due to the relativistic nature of the jets. This is best seen graphically, once some definitions have been made:

If we define the Lorentz factor, $\Gamma$ in the usual way:

[^1]\[

$$
\begin{equation*}
\Gamma=\frac{1}{\sqrt{1-\left(\frac{v}{c}\right)^{2}}} \tag{1.6}
\end{equation*}
$$

\]

Then we can define the Doppler boosting factor, $\delta$ as:

$$
\begin{equation*}
\delta=\frac{1}{\Gamma\left(1-\frac{v}{c} \cos \theta\right)} \tag{1.7}
\end{equation*}
$$

Where $v$ is the velocity of the source. Now if we imagine a polar coordinate space with an AGN source at the centre and a line of sight joining it to an observer on the earth, he/she will see Doppler boosted emission as they look down the forward jet from the AGN. As the the polar plot in Figure 1.4 demonstrates, emission from the source is highly beamed close to the line of sight at $0^{\circ}$. In this plot, theta is the viewing angle of observation (varying from 0 up to $2 \pi$ radians) and delta is the Doppler boosting factor defined above.

Figure 1.4: Doppler Beaming in Relativistic Jets

### 1.4.5 Superluminal Motion

Firstly, it is important to be clear on what is meant by a knot or jet component. These are bright and compact features that can be distinguished in VLBI images of relativistic jets. There is a possibility that components might be hydrodynamical features such as internal shocks (Hardcastle, 2007).

Components that are visible along relativistic jets can exhibit a phenomenon called superluminal motion. This is a geometric effect that can lead to apparent component velocities greater than that of light according to the observer. The effect is most significant for small angles between the relativistic jet and the line of sight.

Consider the following case, with a relativistic jet component moving from one observed position to another:

$\bar{V}$ Very distant observer

Figure 1.5: The Geometric Framework for Superluminal Motion
Initially, the jet component may emit a photon that is detected by an observer at a large distance away. This distance shall be denoted as $d$. The component travels at a velocity $v$ for a time $\Delta t$ and at an angle $\theta$ with respect to the initial line of sight.

Thus, it is possible to deduce that Photon 1 takes a time $t_{1}=\frac{d}{c}$ to reach the observer. Also, Photon 2 is in transit for a time $t_{2}=\frac{d-v \Delta t \cos (\theta)}{c}$ before reaching the same observer. But Photon 2 was emitted a time $\Delta t$ after Photon 1 . Therefore Photon 2 actually reaches the observer after a time $t_{2}=\Delta t+\frac{d-v \Delta t \cos (\theta)}{c}$.

In the time $\Delta t$ between the two photon emissions, the component traveled a transverse (from the observer's point of view) distance $v \Delta \operatorname{tsin}(\theta)$. Hence the apparent transverse velocity as seen by the observer is $v_{a p p}=\frac{v \Delta t \sin (\theta)}{t_{2}-t_{1}}$. With substitution and canceling of terms the following final expression can be obtained for the apparent transverse velocity, $v_{a p p}$ :

$$
\begin{equation*}
v_{a p p}=\frac{v \sin (\theta)}{1-\frac{v \cos (\theta)}{c}} \tag{1.8}
\end{equation*}
$$

It can be noticed that as $v \cos (\theta)$ tends towards $c, v_{a p p}$ tends to infinity.
$v_{\text {app }}$ can be plotted to see its angular dependence, as has been implemented in Figure 1.6. Here, theta is the angle that was previously defined, shown now in radians. It ranges from 0 up to $\pi$ on the graph.

Figure 1.6: Angular Dependence of Superluminal Motion in Relativistic Jets
The graph shows that superluminal motion is most significant at smaller angles between the relativistic jet and the line of sight. No superluminal motion is observed at 0 radians since along the line of sight there will be no transverse motion observed. There is a singularity when $v=c$ that can be seen on the graph.

By maximising $V_{a p p}$ in (1.8) with respect to $\theta$ in the usual way we obtain $\cos (\theta)=\frac{v}{c}$ and by manipulating this, $\sin (\theta)=\frac{1}{\Gamma}$. Via a small angle approximation for $\theta$ (given that the line of sight is close to the jet axis) one can show that the optimal viewing angle for superluminal motion is:

$$
\begin{equation*}
\theta \sim \frac{1}{\Gamma} \tag{1.9}
\end{equation*}
$$

This is the same as the width of a Doppler beamed cone of synchrotron emission. One can perform a number of other different exercises to derive similarly useful expressions within this context:

1. By substitution of $\cos (\theta)=\frac{v}{c}$ and $\sin (\theta)=\frac{1}{\Gamma}$ above into (1.8) we can derive an
expression for the maximum value of $V_{a p p}$ :

$$
\begin{equation*}
V_{a p p}^{\max }=v \Gamma \tag{1.10}
\end{equation*}
$$

Note that this expression depends only upon $v$. Taking $v=0.999 c$ for a numerical result we obtain $V_{a p p}^{\max }=22.34 c$.
2. Setting $V_{\text {app }}=c$ again and using $\cos (\theta)=\frac{v}{c}$ and $\theta_{\max }=45^{\circ}$ we can derive the minimum source velocity, v for superluminal motion:

$$
\begin{equation*}
v_{m i n}=\frac{c}{\sqrt{2}} \tag{1.11}
\end{equation*}
$$

### 1.5 Thesis Summary

This thesis presents a study of 29 AGN jet sources studies over three epochs with the VLBA. Further investigation is undertaken into non-linear jet structures in two of the sources in particular.

Chapter 1 provides an introduction to AGN and then discusses Blazar jets in more detail, with attention paid to some physical mechanisms that are relevant and important. Chapter 2 looks at some basic interferometry concepts before going on to cover some details with respect to mapping, the VLBA and calibration issues. Chapter 3 presents the results of the mapping and the model fitting. A complete derivation of a physical model for helical jet structures is given in Chapter 4. In Chapter 5, plots are shown that demonstrate an attempt to apply the physical model derived to model fitting results for two of the sources imaged. Chapter 6 gives principle results of the kinematic study. The final chapter gives the final results of the work along with discussion and a consideration of possible further study.

## Chapter 2

## Observational Techniques

In this chapter I describe the VLBA as an array of interferometers and give an account of the underlying principles that allow it to image sources such as Blazars.

### 2.1 Interferometry Basics

The principle benefit of interferometry in terms of imaging is resolution. With a single radio dish the resolution is approximately the wavelength of the signal divided by the dish diameter. However, for an interferometer the resolution is approximately the wavelength of the signal divided by the baseline length (the distance between the two dishes in the interferometer). Therefore interferometry will yield improved resolution.

Let us take the simple example of a two element interferometer as shown in Figure 2.1. The two antennas shall be labeled with the numbers 1 and 2 and are separated by the baseline length, $s$. There is a path difference between the two signals, $P$. This varies throughout an observing day due to the change in direction of the received signal.

Kitchin (2003) discusses two causes of the path difference $P$. Firstly, there will be delays in the electronics and cables connecting the antennae to the central processing unit. Secondly, the angle of inclination of the source to the line joining the two antennae. The former is usually small and can be ignored or corrected for. The latter will change as the rotation of the earth alters the inclination angle. The rate of change of $P$ varies throughout an observing day due to interference in the source signal.

The path difference also varies because the effective separation of the antennae, $d$ (the apparent separation of the antennae as seen from the direction of the source) varies in time.

The change in $d$ causes the resolution of the interferometer to change and this will alter the uv coverage with the interferometer's tracks moving either outward or inward depending on a positive or negative rate of change of $d$. uv coverage shall be covered in more detail in the next section.

Figure 2.1: A basic interferometer arrangement (Kitchin, 2003)

## 2.2 uv Coverage, Visibilities and Source Brightness Distribution

Two antennae arranged upon an east-west line will follow a circular track perpendicular to the earth's rotational axis. Therefore for convenience, the uv plane is taken to be perpendicular to the earth's axis. As mentioned in the previous section, a range of tracks will be traced out upon the uv plane depending on the geometry of the interferometer as it is with respect to the source.

The VLBA's constituent antennae observe a source simultaneously and at discrete points in time in order to build up a picture of the brightness distribution of a source. The discrete samples are called visibilities. It is these that are measured by the VLBA. The Fourier transform of a function is always symmetrical. Therefore when an interferometer makes an observation of a source, two visibilities are plotted about the centre of the uv plane (that is, with the centre of the uv plane in between the two points). As the earth rotates the antennae comprising each interferometer trace out curves in the Fourier or uv plane. It is in this plane that the VLBA's interferometers operate. The array tracks are formed as follows. Consider a single baseline array (two dishes). Due to the earth's
rotation they trace out curves in the uv plane on the sky as shown in Figure 2.2.

Figure 2.2: uv Coverage
Here, $u$ and $v$ are effectively coordinates on the sky. The centre of the plot represents the $(0,0)$ position in terms of $u$ and $v$. Coordinates are always set up such that East points to the left and North upwards. Scales are in mas.

The technique of aperture synthesis in the case of the VLBA allows constituent interferometers to contribute their own visibilities (Fourier components) to the uv plane for a source. Longer baselines contribute higher angular frequency and therefore higher resolution information about a source and vice versa for shorter baselines. With a network of antennae, good uv plane sampling allows a good image of the source without sidelobe features contaminating the beam (hence the term dirty beam in such a case). These result from gaps in the uv coverage. A single twelve hour observation by a two-element interferometer samples components of the Fourier transform of the field of view covered in the uv plane. In reality, a series of twelve hour observations are made using all of the available baseline lengths. The uv plane is then sampled out to the maximum baseline length, which gives the highest resolution information.

The distribution of visibilities $V(u, v)$ and the brightness distribution of the source on the sky $B(x, y)$ form a Fourier pair such that the following equations can be written (Reynolds, 2002):

$$
\begin{align*}
& V(u, v)=\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} B(x, y) e^{2 i \pi(u x+v y) d x d y}  \tag{2.1}\\
& B(x, y)=\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} V(u, v) e^{-2 i \pi(u x+v y) d u d v} \tag{2.2}
\end{align*}
$$

Therefore, given that the distribution of visibilities are measured by the interferometer, an image of the brightness distribution of a source can be found by taking the Fourier transform.

### 2.3 Cleaning and Self-Calibration

The making of VLBI maps is a loop process in terms of cleaning and self-calibration. Figure 2.3 indicates the extent of this. Cleaning VLBI maps deconvolves the dirty map. It brings together a number of steps which are outlined below (Högbom, 1974):

1. Calculate the dirty beam by taking the Fourier transform of the uv coverage sampling. In addition, find the dirty map by taking the Fourier transform of the visibility data.
2. At the point where the dirty map reaches its maximum intensity, subtract off the dirty beam to leave a residual map. The dirty beam should be normalised to a factor between zero and unity (the loop gain), multiplied by the maximum of the dirty map.
3. Repeat the subtractions with the dirty beam, each time taking the residual map from the previous iteration as the dirty map. Stop when the maximum intensity of the dirty map is no longer significant with respect to the general noise level.
4. Take the final residual map, and return to it all of the subtracted (clean) components with their respective positions and amplitudes.

| ERRORS. |

Figure 2.3: A simple diagram of the cleaning process undertaken during VLBI map making

For instruments such as the VLBA, closure phase is utilised. The atmospheric conditions cause phase delays that may be canceled out via the closure phase of three antennae.

Following Kitchin (2003), we can consider a simple three element interferometer. We indicate that the phases for the three baselines independent of atmospheric effects are $\phi_{12}, \phi_{23}$ and $\phi_{31}$. Finally, we show the atmospheric phase delays as $a_{1}, a_{2}$ and $a_{3}$. The observed phases are then:

$$
\begin{align*}
& \phi_{12}+a_{1}-a_{2}  \tag{2.3}\\
& \phi_{23}+a_{2}-a_{3}  \tag{2.4}\\
& \phi_{31}+a_{3}-a_{1} \tag{2.5}
\end{align*}
$$

The closure phase is then given by the phase sum around the baselines and it can be seen that the atmospheric phase delays will cancel completely to leave:

$$
\begin{equation*}
\phi_{123}=\phi_{12}+\phi_{23}+\phi_{31} \tag{2.6}
\end{equation*}
$$

Thus the closure phase is independent of the effects of atmosphere and this reduces the number of unknowns in the imaging procedure.

There are drawbacks that come with the use of closure phase. In a triangle of antennas, one must be taken as a reference antenna, such that the phases of the other two are measured relative to it. The problem here is that no measure of absolute phase is possible. The main disadvantage of closure phase is that it removes atmospheric phase delays at the expense of source position (Jennison, 1958).

### 2.4 Hybrid Mapping

Hybrid mapping as a procedure involves iterative self-calibration with a view to estimating unknown phase and/ or amplitude errors at each antenna. The errors in question do not affect closure phases and amplitudes.

It may be possible to use three programs for hybrid mapping. The first should correct the visibilities in the input file by comparison with the predictions of an input model. It should also estimate the calibration corrections to minimise the disagreement between the corrected visibilities and the user's input model. A second program should make a dirty map and then a CLEAN algorithm should clean the dirty map to produce an array of delta functions that can be used as a new starting model.

### 2.5 The Very Long Baseline Array (VLBA)

The VLBA is a network of amplitude interferometers situated across America. It can achieve resolutions of mas or even micro-arcseconds thanks to the large distances between antennas (see Figure 2.4). In the case of the VLBA, signals are recorded onto tapes at each station. There is a separate correlation centre that processes all of the data (tapes) from the constituent antennas.

Data from the VLBA was utilised in order to produce high resolution maps of close to thirty relativistic jet sources. Figure 2.4 shows how the antennas making up the VLBA are distributed across the United States.

### 2.6 Stokes Parameters, D-terms and the Instrumental Polarisation

For frequency bands above 1 GHz , Cassegrain feeds are located on a circle at the top of a feed cone. The outputs of the feeds are circular waveguide apertures. From these the

Figure 2.4: The constituent antennas of the VLBA (image taken from www.vlba.nrao.edu/sites).
signals pass to the polarisers (waveguide devices) that produce outputs corresponding to opposite circularly polarised components (Thompson, 1995). Circular feed correlators can produce four cross correlations. The time averaged expressions are shown below (Burke and Graham-Smith, 2002) in terms of the Stokes parameters.

$$
\begin{align*}
& \left\langle R R^{*}\right\rangle=I+V  \tag{2.7}\\
& \left\langle R L^{*}\right\rangle=Q+i U  \tag{2.8}\\
& \left\langle L R^{*}\right\rangle=Q-i U  \tag{2.9}\\
& \left\langle L L^{*}\right\rangle=I-V \tag{2.10}
\end{align*}
$$

With these equations laid out, it is appropriate to explain the significance of each of Stokes parameters. These are used to describe polarised radiation. $V$ essentially demonstrates
the circular component of polarisation, $Q$ and $U$ describe the linear component and $I$ gives the total intensity (Garcia, 1995). The linear polarisation is given as $P=Q+i U=$ $m I e^{2 i \chi}$ where $m$ is the percentage polarisation and $\chi$ is the Electric Vector Position Angle or EVPA. For polarised radiation, this is the plane in which the electric field lies. It is perpendicular to the plane of the magnetic field. The polarised flux density, $p$ and the EVPA are therefore given as follows:

$$
\begin{gather*}
p=m I=\sqrt{Q^{2}+U^{2}}  \tag{2.11}\\
\chi=\frac{1}{2} \tan ^{-1} \frac{U}{Q} \tag{2.12}
\end{gather*}
$$

The RR and LL cross-correlations provide information on the total intensity for a source, $I$. Polarisation information (in the form of data for Stokes parameters $Q$ and $U$ ) for each source is provided by RL and LR cross-correlations.

### 2.7 Calibration for Imaging

### 2.7.1 Initial Calibration

## Initial Amplitude Calibration:

It is necessary to perform an initial amplitude calibration since the measured correlation coefficients are in arbitrary units. To convert to a unit such as $J y$ the following expression may be utilised for the correlated flux density on baseline i-j, $S_{\text {cij }}$ (Walker, 2004):

$$
\begin{equation*}
S_{c i j}=\rho \frac{A}{\eta_{s}} \sqrt{\frac{T_{s i} T_{s j}}{K_{i} K_{j} e^{-\tau_{i}} e^{-\tau_{j}}}} \tag{2.13}
\end{equation*}
$$

The measured coefficients from the correlators are given as $\rho$ here. $A$ is a correlator specific scaling factor. $\eta_{s}$ represents the system efficiency. $T_{s}$ represents the system temperature at an antenna. $K$ is the gain in units of degrees Kelvin per Jansky. This incorporates the antenna gain curve, which gives the distortion of the antenna due to gravity as a function of elevation. $e^{-\tau_{j}}$ indicates absorption in the atmosphere.

Fringe Fitting:
Instrumental frequency phase offsets can create slopes in phase within each of the IFs (intermediate frequencies). ${ }^{1}$ This can present a problem when it comes to averaging. To avoid cancellation of phases during frequency and time averaging it is necessary to remove slopes in phase with a fringe fit.

[^2]After the first fringe fit, phases can be flat within the IFs but disjointed between them due to atmospheric effects. Before averaging, this must also be corrected for with another fringe fit.

### 2.7.2 EVPA Calibration

The EVPA is calculated from Stokes $Q$ and $U$ parameters as follows:

$$
\begin{equation*}
E V P A, \chi=\frac{1}{2} \arctan \frac{U}{Q} \tag{2.14}
\end{equation*}
$$

A final step in the imaging of VLBI sources is a correction for an rotation in the EVPAs that applies to all images made. Prior to this step, all EVPAs will be correct relative to each other, but will be rotated by a fixed amount that must be calculated and corrected for (assuming the correction is not zero).

The EVPA rotation arises due to a difference in phase at the reference antenna. This phase difference is between the right and left hand gains and can be denoted as $\theta$. The EVPA rotation is then equal to $\theta / 2$.

There are a number of ways to tackle this calibration issue:

1. Integrated polarisation position angle comparison with the Very Large Array (VLA). The integrated EVPA along a source should be the same as the EVPA as measured by the VLA, a lower resolution instrument. Observation times need to be as consistent as possible in this comparison. The EVPAs of many Blazars can be variable on timescales as short as (or shorter than) days.
2. The EVPA of fairly stable components in sources. This is a comparison with the source observed in other epochs. Some sources contain components with EVPAs that are more or less stable of multiple epochs of observation. At the time of imaging, 0954+658 and 1730-130 were examples of sources that contained such components.
3. Core-dominated polarisation sources. For sources where the polarisation is sufficiently compact, it is possible to make a direct EVPA comparison with the VLA to check for a correction. Again, the same considerations on observation times are necessary. Examples at the time of imaging were 0420-014 and OJ287.

Analyses of the EVPA correction required for the August and November 2007, as well as the January 2008 epochs were undertaken. It was decided that no correction to EVPAs was necessary for any of the three epochs after this analysis.

### 2.7.3 Instrumental Polarisation

The VLBA utilises circularly polarised feeds. There will be some degree of leakage between the feeds. This means that right circular polarisation (RCP) can contaminate the
left circular polarisation (LCP) feed and vice versa. Polarisation leakage will corrupt any polarisation maps that are made unless it is dealt with.There will be an effect upon the total intensity image, but this will not be as significant.

It is possible to deal with the instrumental polarisation by consideration of D-terms. The voltages at the RCP and LCP feeds can be expressed as follows:

$$
\begin{align*}
& V_{R}=G_{R}\left(E_{R} e^{-i \phi}+D_{R} E_{L} e^{i \phi}\right)  \tag{2.15}\\
& V_{L}=G_{L}\left(E_{L} e^{i \phi}+D_{L} E_{R} e^{-i \phi}\right) \tag{2.16}
\end{align*}
$$

Source

Figure 2.5: Geometric demonstration of the parallactic angle.
The G terms are gains for the RCP and LCP feeds, which may be determined by selfcalibration. $\phi$ indicates the parallactic angles. These describe the rotation of the feeds of an altitude-azimuth telescope relative to a source that is tracked across the sky. A geometrical appreciation of the parallactic angle is given in Figure 2.5.

The RL and LR correlations complete with D-terms can be shown as:

$$
\begin{gather*}
R_{i} L_{j}^{*}=G_{R i} G_{L j}^{*}\left[P+I\left(D_{L j}^{*} e^{2 i \phi_{j}}+D_{R i} e^{2 i \phi_{i}}\right)\right]  \tag{2.17}\\
L_{i} R_{j}^{*}=G_{L i} G_{R j}^{*}\left[P+I\left(D_{R j}^{*} e^{-2 i \phi_{j}}+D_{L i} e^{-2 i \phi_{i}}\right)\right] \tag{2.18}
\end{gather*}
$$

The above expressions are valid for small D-term values of a few percent or less. Given a good range of parallactic angles it is possible to determine the D-terms. Clean components analysis can be performed whereby jet components are identified within a defined perimeter. In these regions it is assumed that the polarisation is constant. This is a fairly safe assumption to make across a jet component. In implementing this procedure, equations containing the D-terms can be constrained. This allows calculation of the D-terms themselves.

## Chapter 3

## Results

### 3.1 Source List

The source list given was part of a long term blazar monitoring scheme undertaken by the Boston University Blazar Group. Long term observation is important for Blazar study in order to investigate their typical behaviours (Hovatta et al., 2008).

Data was analysed for the following sources: $0235+164,0336-019,0420-014,0528+134$, $0716+714,0735+178,0827+243,0829+046,0836+710,0954+658,1127-145,1156+295,1219+285$, $1222+216,1406-076,1510-089,1611+343,1622-297,1633+382,1730-130,3 C 111,3 C 273$, 3C279, 3C345, 3C446, 3C454.3, BL Lac, CTA102 and OJ287.

### 3.2 Observational Details

For the 43GHz observations on the 6th August 2007, the 1st November 2007 and the 17th January 2008 I include a $\log$ of the observational scans of the sources studied. The log gives time ranges for the scans of each source along with other information.

### 3.2.1 August 2007 Epoch

Figure 3．24：Log of the January 2008 observation details．

### 3.3 VLBI Maps

VLBI maps were produced for three distinct epochs of observation: August 2007, November 2007 and January 2008. The results are shown in terms of each source and prior to calibration of their EVPAs. The goal of this work does not involve the analysis of polarisation structures. They appear only to demonstrate the polarisation results that were obtained in the process of making VLBI maps. Nothing further will be added to describe the calibration of EVPAs, as it is not a necessary part of this work.

For all of the sources, there are more epochs of observation available to be viewed at www.bu.edu/blazars/VLBAproject.html. This is a part of the Boston University Blazar Group website.

Some of the mapping work that I present in this thesis (for 3C279) was included in Larionov et al. (2008). This work indicates that the source may contain a helical magnetic field that extends 20 pc past the 43 GHz core.

## $0235+164$

Polarisation structure can be seen in the core of this source in all but the January 2008 epoch. The core dominates the images, with more diffuse emission also visible. There is a significant drop in the peak flux of the source in the January 2008 epoch.

Figure 3.25: August 2007 VLBI Map of $0235+164$. For polarisation vectors: 1 mas $=$ $3.57 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.26: November 2007 VLBI Map of $0235+164$. For polarisation vectors: 1 mas $=$ $3.57 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.27: January 2008 VLBI Map of 0235+164.

## 0336-019

This is a more extended source. Many components can be seen in the images, although less structure separated from the core is visible. Polarisation can be seen in the core and first component in the August and November 2007 images. Judging by the angles of the polarisation vectors around the core in January 2008 however, it is not as clear as to whether real polarisation is present along the jet.

Figure 3.28: August 2007 VLBI Map of 0336-019. For polarisation vectors: 1 mas $=$ $5.00 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.29: November 2007 VLBI Map of 0336-019. For polarisation vectors: 1 mas = $5.00 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.30: January 2008 VLBI Map of 0336-019. For polarisation vectors: 1 mas $=$ $2.50 \times 10^{-1} \mathrm{Jy} /$ beam.

## 0420-014

The most interesting feature of the three images of this source is manifest in the apparent yet significant swing of the jet in the January 2008 epoch. There is a drop in the peak flux of about 0.5 Jy that accompanies the drop. Polarisation is prominent in the core of the source across the three epochs.

Figure 3.31: August 2007 VLBI Map of 0420-014. For polarisation vectors: 1 mas $=$ $1.00 \times 10^{0} \mathrm{Jy} / \mathrm{beam}$.

Figure 3.32: November 2007 VLBI Map of 0420-014. For polarisation vectors: 1 mas $=$ $6.25 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.33: January 2008 VLBI Map of 0420-014. For polarisation vectors: 1 mas $=$ $5.00 \times 10^{-1} \mathrm{Jy} /$ beam.

The peak flux for this source exhibits a drop that can be seen in the final VLBI map. Polarisation appears to occupy the core and (tentatively) the first component in August and November 2007 though there is no polarisation seen in the first component in the January 2008 epoch. In terms of the core polarisation, there appears to be a gradual anticlockwise rotation of the EVPAs across the epochs.

Figure 3.34: August 2007 VLBI Map of $0528+134$. For polarisation vectors: 1 mas $=$ $1.00 \times 10^{0} \mathrm{Jy} /$ beam.

Figure 3.35: November 2007 VLBI Map of $0528+134$. For polarisation vectors: 1 mas $=$ $1.25 \times 10^{0} \mathrm{Jy} /$ beam.

Figure 3.36: January 2008 VLBI Map of $0528+134$. For polarisation vectors: 1 mas $=$ $2.50 \times 10^{-1} \mathrm{Jy} /$ beam.

## $0716+714$

Over the three epochs, the peak flux jumps from 1.02 Jy to 2.61 Jy before falling to 0.738 Jy . Again, no polarisation vectors can be seen in the January 2008 epoch, though the core is clearly polarised in August 2007 and November 2007.

Figure 3.37: August 2007 VLBI Map of $0716+714$. For polarisation vectors: 1 mas $=$ $5.00 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.38: November 2007 VLBI Map of $0716+714$. For polarisation vectors: 1 mas $=$ $8.33 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.39: January 2008 VLBI Map of $0716+714$. For polarisation vectors: 1 mas $=$ $3.57 \times 10^{-1} \mathrm{Jy} /$ beam.

An image from the November 2007 epoch was the only success in terms of mapping this source. As can be seen, the beam size is very large. This is likely a reflection of how much data was rejected by the global fringe fit in AIPS.

Most of the data for the source in August 2007 was rejected by the global fringe fit (AIPS task fring). Only 150 good solutions were found, with 1146 failed solutions. This caused major problems. Only a very small amount of data remained and this was present in only a few IFs that had survived the global fringe fit. There were many visibilities available to use for this source initially. Perhaps it was too weak ( $\sim 0.2 \mathrm{Jy}$ ) for fring to operate on it without removing most of the data. Assuming that there would have been a low signal-to-noise ratio for this source, not much structure would have been observable given how relatively weak it is.

Therefore it was deemed impossible to adequately image the source.
Most of the January 2008 data for this source was rejected by the global fringe fit that was implemented. Only 187 good solutions were found, with 1021 failed solutions. Serious problems resulted from this. Some of the antennas had very little data in DIFMAP that had not been lost in the global fringe fit. The rest of the antennas had no data at all. The source may have been too weak ( $<0.3 \mathrm{Jy}$ ) for fring to operate on it adequately.

The residual map of this source showed the core to be too close to the noise level of the image to be distinguished as real. Therefore the judgment was made that it was not worthwhile to image in this case.

There is a general decrease in the peak flux of this source looking through the epochs. Polarisation vectors are present in the 2007 epochs (August and November) though there is a large rotation of the EVPAs between these two epochs. This raises questions of whether a new component was being introduced. The component due east of the core in January 2008 could be such a new component, although such a statement would require further investigation in order to be convincing. Polarisation vectors are shown in the core in January 2008 for this source but are likely to be noise overlaying the core structure. The structure of the polarisation vectors is rather tenuous around the core.

Figure 3.40: November 2007 VLBI Map of $0735+178$.

Figure 3.41: Final VLBI Map of $0827+243$. For polarisation vectors: 1 mas $=5.00 \times 10^{-1}$ Jy/beam.

Figure 3.42: November 2007 VLBI Map of $0827+243$. For polarisation vectors: 1 mas $=$ $2.50 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.43: January 2008 VLBI Map of $0827+243$. For polarisation vectors: 1 mas $=$ $2.50 \times 10^{-1} \mathrm{Jy} /$ beam.

No polarisation could be imaged for this source and furthermore imaging was not possible at all for the January 2008 epoch. The maps that were produced have poor resolution resulting from large beam sizes. The cause of this is likely to be the loss of data following the global fringe fit for this source.

Initially, work on this source in the August 2007 epoch was halted due to the fact that there was no clarity or structure in the preliminary image. The reason for this was the very small amount of data left to work with after the global fringe fit. In spite of this, imaging of the source was tried again. As can be seen from the large beam size in Figure 3.44, resolution was lost for this source due to the lack of data mentioned above. All that resulted from the imaging was a central region with no extended emission (some is present however in the comparison image). Due to the lack of data for this source after the global fringe fit, it was not worth an attempt to image any polarisation in the August 2007 epoch.

A lot of the January 2008 data for this source was rejected by the global fringe fit that was made during the analysis stage. Only 153 good solutions were found, with 1111 failed solutions. This caused major problems. There was no data available for any antennas in DIFMAP. The source may be too weak ( $<0.3 \mathrm{Jy}$ ) for fring to operate on it currently. It was hence not possible to image this source with the data from the January 2008 epoch.

Figure 3.44: August 2007 VLBI Map of 0829+046.

Figure 3.45: November 2007 VLBI Map of 0829+046.

This source appears as a dominant core with extended weak emission in August 2007. In the latter two epochs some components can be seen to be emerging from the core region; they are beginning to separate from it. There is not evidence of particularly strong polarisation in the core across the epochs shown. In fact, in the August 2007 image the polarisation is likely to be noise judging by the distribution of the vectors in the core region.

Figure 3.46: August 2007 VLBI Map of $0836+710$. For polarisation vectors: 1 mas $=$ $3.57 \times 10^{-1}$ Jy/beam.

Map center: RA: 0841 24.365, Dec: +705342.172 (2000.0)
Map peak: $0.951 \mathrm{Jy} /$ beam
Contours \%: -0.15 0.150 .30 .61 .22 .44 .89 .6
Contours \%: 19.238 .476 .8
Beam FWHM: $0.241 \times 0.169$ (mas) at $-21.7^{\circ}$

Figure 3.47: November 2007 VLBI Map of $0836+710$. For polarisation vectors: 1 mas $=$ $2.50 \times 10^{-1}$ Jy/beam.

Figure 3.48: January 2008 VLBI Map of $0836+710$. For polarisation vectors: 1 mas $=$ $2.50 \times 10^{-1}$ Jy/beam.

Again there is a significant drop in the peak flux going into the January 2008 epoch. For this source the drop is from $1.12 J y$ to $0.495 J y$. The polarisation in August 2007 resides predominantly in the core with some vectors in the first component (these are too weak to be realistically considered as noise). In the November 2007 epoch there is also core polarisation but this appears to extend into the first component. The polarised intensity image produced for this source suggests that this extended emission might be real. In the final image, there is again core polarisation that extends into the first component. The polarised intensity image for this source indicates that the extended polarisation is quite possibly real.

Figure 3.49: August 2007 VLBI Map of $0954+658$. For polarisation vectors: 1 mas $=$ $5.00 \times 10^{-1} \mathrm{Jy} / \mathrm{beam}$.

Figure 3.50: November 2007 VLBI Map of $0954+658$. For polarisation vectors: 1 mas $=$ $8.33 \times 10^{-1}$ Jy/beam.

Figure 3.51: January 2008 VLBI Map of $0954+658$. For polarisation vectors: 1 mas $=$ $3.13 \times 10^{-1}$ Jy/beam.

## 1127-145

The January 2008 image has a very large beam size that has caused poor resolution. As has been mentioned before, this is likely due to a loss of data following the global fringe fit for this source in January 2008.

Extended weak structure was seen in this source several mas from the core. The polarised intensity in the core appears to be real, but the other polarisation structures are approximately at the noise level of Figure ??. It is worth mentioning that there were almost as many failed solutions in the global fringe fit as there were good solutions. Some of the RR and LL parallel polarisation phases had significant scatter within their IFs. A handful of IFs were missing any data at all amongst the RR, LL, RL and LR polarisations. This was probably due to the amount of failed solutions in the global fringe fit. In turn, this was likely to be the cause of the small amount, or complete lack of data left over when inspecting each antenna during the analysis of this source. The lack of good quantities of data for many antennas may have caused a loss of resolution in images for this source.

Polarisation in or close to the core in August and November 2007 is close to noise level in the accompanying polarised intensity images.

Figure 3.52: August 2007 VLBI Map of 1127-145. For polarisation vectors: 1 mas = $5.00 \times 10^{-1} \mathrm{Jy}$ /beam.

Figure 3.53: November 2007 VLBI Map of 1127-145. For polarisation vectors: 1 mas = $5.00 \times 10^{-1}$ Jy/beam.

Figure 3.54: January 2008 VLBI Map of 1127-145. For polarisation vectors: 1 mas = $3.57 \times 10^{-1}$ Jy/beam.

The extended emission in January 2008 for this source is strange in that it is directed in two directions away from the core. The extended emission nearly due east of the core is rather weak so might not be real. The slightly stronger emission moving away from the core in a northwesterly direction might demonstrate a swing in the jet from its general direction in the other two earlier epochs.

This is another source oriented close to the line of sight. It is not possible to say with any certainty that any of the polarisation is real. It is all at the approximate noise level of the map. This is true despite some of the 'polarisation' lying near to the central core region and along the apparent jet direction. There were more failed solutions in the global fringe fit than there were good solutions here. Some of the RR and LL parallel polarisation phases had scatter within their IFs. Also, even after the global fringe fit there was some slight sloping of some of these phases within their IFs. Some IFs had no data at all amongst the RR, LL, RL and LR polarisations. This was probably due to the amount of failed solutions in the global fringe fit. In turn, this was likely to be the cause of the small amount, or complete lack of data left over when inspecting each antenna during the analysis of this source. The lack of good quantities of data for many antennas may have caused a loss of resolution in images for this source.

The core polarisation in November 2007 and January 2008 is likely to be real since the polarised intensity image shows significant levels in the core in these epochs.

Map center: RA: 1159 31.834, Dec: +291443.827 (2000.0)
Map peak: $0.338 \mathrm{Jy} /$ beam
Contours \%: -0.75 0.75 1.53612244896
Beam FWHM: $0.412 \times 0.186$ (mas) at $-22.4^{\circ}$

Figure 3.55: August 2007 VLBI Map of $1156+295$. For polarisation vectors: 1 mas $=$ $5.00 \times 10^{-1}$ Jy/beam.

Figure 3.56: November 2007 VLBI Map of $1156+295$. For polarisation vectors: 1 mas $=$ $2.50 \times 10^{-1}$ Jy/beam.

Figure 3.57: January 2008 VLBI Map of $1156+295$. For polarisation vectors: 1 mas $=$ $3.13 \times 10^{-1}$ Jy/beam.

This is one of the weaker jets (according to data from the Boston University Blazar Group this source never reaches above $0.5 J y$ in 2007 or 2008). It was only possible to image this source from the January 2008 data. As can be seen in Figure 3.58 the resolution is very poor.

Most of the August 2007 data for this source was rejected by the global fringe fit. Only 129 good solutions were found, with 1039 failed solutions. This caused major problems. Very little data was left to see and this was present in only one IF that had survived the global fringe fit. There were many visibilities available to use for this source initially however. Perhaps it was too weak ( $<0.2 \mathrm{Jy}$ ) for fring to operate on it successfully. As was the case for 0735+178 (another weak source), not much structure would have been observable. Therefore it was deemed impossible to adequately image this source.

Imaging was not possible from the November 2007 data either since most of the data for this source was rejected by the global fringe fit that was implemented, causing a large loss of data. In fact, there was none left to image with at all in DIFMAP. This was likely to be another case where the source is too weak for fring to be able to operate on it. No results were obtained from the August 2007 data for this source as has been indicated previously. The fact that no data was available from the St. Croix antenna is likely to have hindered the imaging of this source.

It was possible to image this source for the first time in the January 2008 epoch (after two previously failed attempts in August 2007 and November 2007). Only the core could be resolved, whereas extended emission is visible in the comparison image. The final map is very poor here.

## $1222+216$

This is another one of the weaker jets (as for 1219+285, according to data from the Boston University Blazar Group this source never reaches above $0.5 J y$ in 2007 or 2008).

Most of the August 2007 data for this source was rejected by the global fringe fit. Only 128 good solutions were found, with 1040 failed solutions. The remaining data was present in only one IF that had survived the global fringe fit. Again, there were many visibilities available to use for this source initially but it was probably too weak ( $<0.2 \mathrm{Jy}$ ) for fring to adequately operate on it. Not much structure would have been observable for such a weak source. Therefore it was also deemed impossible to image this source to a satisfactory standard.

Imaging was not possible for this source in November 2007 either. Again, a large loss of data resulted from the global fringe fit. Not enough data remained for imaging to take place.

This was the second source that I managed to image for the first time in January 2008 (after two unsuccessful attempts in August 2007 and November 2007). Again, it was only possible to resolve the core, but structure separated from the central region is seen in Figure ??.

Figure 3.58: January 2008 VLBI Map of $1219+285$. For polarisation vectors: 1 mas $=$ $1.25 \times 10^{0} \mathrm{Jy} /$ beam .

## 1406-076

This source maintains a fairly steady peak flux in the epochs shown. A large beam size for the January 2008 epoch yields a poor resolution image with no significant structure. The lack of any data from a handful of the contributing antennas in this epoch likely played a large part in this problem. This is in constrast to the 2007 images, which show some extended compact structure.

In August 2007, there were many more failed solutions in the global fringe fit than there were good solutions here. Most of the RR and LL parallel polarisation phases had significant scatter within their IFs. Also, even after the global fringe fit there was some slight sloping of most of these phases within their IFs. All of the RL and LR cross polarisation phases were random, which may account for the lack of measurable polarisation for this source. A handful of IFs were missing any data at all amongst the RR, LL, RL and LR polarisations. This was probably due to the amount of failed solutions in the global fringe

Figure 3.59: January 2008 VLBI Map of $1222+216$. For polarisation vectors: 1 mas = $5.99 \times 10^{-1}$ Jy/beam.
fit. In turn, this was likely to be the cause of the small amount, or complete lack of data left over when inspecting each antenna during the analysis of this source. The lack of good quantities of data for many antennas may have caused a loss of resolution in images for this source.

Map center: RA: 140856.481 , Dec: -075226.666 (2000.0)
Map peak: $0.299 \mathrm{Jy} / \mathrm{beam}$
Contours \%: -0.5 0.51248163264
Beam FWHM: $0.596 \times 0.274$ (mas) at $-17.7^{\circ}$

Figure 3.60: August 2007 VLBI Map of 1406-076. For polarisation vectors: 1 mas $=$ $5.00 \times 10^{-1}$ Jy/beam.

Figure 3.61: November 2007 VLBI Map of 1406-076. For polarisation vectors: 1 mas = $5.00 \times 10^{-1}$ Jy/beam.

Figure 3.62: January 2008 VLBI Map of 1406-076. For polarisation vectors: 1 mas = $8.33 \times 10^{-1} \mathrm{Jy} /$ beam.

## 1510-089

The more intense emission from this source is confined to a compact area near the core, with examples of some lower intensity emission further from the core. The polarisation in the core in the August 2007 map is strange in that it does not maintain the same position angle in this region. The polarised intensity map that accompanies this image reveals two areas of polarised intensity around the core, which partially explains this feature of the final map. There is polarisation in the core of the November 2007 image but it does not appear to be very strong. The polarised intensity image suggests that there is real polarisation in the core though it is not far above noise level. In the final epoch shown, there is polarisation in the core and first component.

Figure 3.63: August 2007 VLBI Map of 1510-089. For polarisation vectors: 1 mas $=$ $5.00 \times 10^{-1}$ Jy/beam.

Figure 3.64: November 2007 VLBI Map of 1510-089. For polarisation vectors: 1 mas = $2.50 \times 10^{-1}$ Jy/beam.

Figure 3.65: January 2008 VLBI Map of 1510-089. For polarisation vectors: 1 mas = $3.13 \times 10^{-1}$ Jy/beam.

## $1611+343$

The January 2008 image shows some interesting structure near to the core; the emission appearing to bend and wave. The core appears to be polarised in all of the epochs though in the November 2007 case this emission does not seem to be very strong. Also, in the January 2008 epoch the polarisation appears to be quite weak and may not be real.

Figure 3.66: August 2007 VLBI Map of $1611+343$. For polarisation vectors: 1 mas $=$ $6.25 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.67: November 2007 VLBI Map of $1611+343$. For polarisation vectors: 1 mas $=$ $4.17 \times 10^{-1}$ Jy $/$ beam.

Figure 3.68: January 2008 VLBI Map of $1611+343$. For polarisation vectors: 1 mas $=$ $3.57 \times 10^{-1}$ Jy/beam.

There is a possibility that the core may lie due east of the brightest component in the January 2008 image. However this is difficult to say with any certainty.This image suffers from a large beam size. With a smaller beam it might be possible to gain a better incite into where the core is situated. It was not possible to image any polarisation at all for this source.

There were almost as many failed solutions in the global fringe fit undertaken for the August 2007 data as there were good solutions for this source. A handful of IFs were missing any data at all amongst the RR, LL, RL and LR polarisations. This was probably due to the amount of failed solutions in the global fringe fit. In turn, this was likely to be the cause of the small amount, or complete lack of data left over when inspecting each antenna during the analysis of this source. The lack of good quantities of data for many antennas may have caused a loss of resolution in images for this source. Indeed, the resolution in the final map in Figure 3.69 is relatively poor. Some extended structure is seen but no measurable polarisation was detected.

Figure 3.69: August 2007 VLBI Map of 1622-297. For polarisation vectors: 1 mas $=$ $6.25 \times 10^{-1}$ Jy/beam.

Figure 3.70: November 2007 VLBI Map of 1622-297. For polarisation vectors: 1 mas = $5.00 \times 10^{-1}$ Jy/beam.

Figure 3.71: January 2008 VLBI Map of 1622-297. For polarisation vectors: 1 mas = $8.33 \times 10^{-1} \mathrm{Jy} /$ beam.

This source has emission that appears to bend sharply near the core. This is perhaps most prominent in the August 2007 and January 2008 epochs. Weak emission appears to entend far from the core though much of what could be construed as jet emission could be noise. The core appears polarised in August 2007 and January 2008. There is polarisation around the core in November 2007 but it appears weak and may well be noise. Considering the August 2007 and January 2008 epochs on their own, there is a rotation in the polarisation position angle in the core by a significant amount.

Figure 3.72: August 2007 VLBI Map of $1633+382$. For polarisation vectors: 1 mas $=$ $3.57 \times 10^{-1}$ Jy/beam.

Figure 3.73: November 2007 VLBI Map of $1633+382$. For polarisation vectors: 1 mas $=$ $2.50 \times 10^{-1}$ Jy/beam.

Figure 3.74: January 2008 VLBI Map of $1633+382$. For polarisation vectors: 1 mas $=$ $3.57 \times 10^{-1}$ Jy/beam.

This source brightens by roughly 0.5Jy between the August and November 2007 epochs. The jet itself appears to bend towards an easterly direction in the first two epochs shown, then straighten up somewhat in January 2008. The polarisation in August 2007 appears to reside in the core and a component approximately due north of the core. However the polarised intensity map reveals that this polarisation is likely to be noise in both cases. The same kind of situation is presented in the November 2007 epoch, but this time the polarisation is more convincing. The core appears to be polarised with fairly prominent polarisation vectors in January 2008. Between the November 2007 and the January 2008 epochs there is a rotation in the position angle of polarisation.

Figure 3.75: August 2007 VLBI Map of 1730-130. For polarisation vectors: 1 mas = $3.57 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.76: November 2007 VLBI Map of 1730-130. For polarisation vectors: 1 mas = $4.17 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.77: January 2008 VLBI Map of 1730-130. For polarisation vectors: 1 mas = $8.33 \times 10^{-1}$ Jy/beam.

## 3C111

This source undergoes a flux increase of around 1 Jy before dropping down to 1.89 Jy in the final epoch shown. This is one of the more extended sources imaged. There is some nice helical structure near the core in January 2008. There is polarised intensity indicated in each of the images of this source. However, the polarised intensity maps indicate that the only strong polarisation in this source is to be found in November 2007.

Figure 3.78: August 2007 VLBI Map of 3C111. For polarisation vectors: $1 \mathrm{mas}=3.57 \times 10^{-1}$ Jy/beam.

Map center: RA: 0418 21.280, Dec: +380135.761 (2000.0)
Map peak: $3.5 \mathrm{Jy} /$ beam
Contours \%: $-0.4 \quad 0.4 \quad 0.8 \quad 1.6 \quad 3.2 \quad 6.4 \quad 12.8 \quad 25.6$
Contours \%: 51.2
Beam FWHM: $0.336 \times 0.16$ (mas) at $-19.5^{\circ}$

Figure 3.79: November 2007 VLBI Map of 3C111. For polarisation vectors: 1 mas $=$ $5.00 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.80: January 2008 VLBI Map of 3C111. For polarisation vectors: 1 mas $=2.50 \times 10^{-1}$ Jy/beam.

This source demonstrates some signs of interesting helical structure in all of the epochs shown. This can be seen along each of the jets in places where the structure appears to meander. This source exhibits a great deal of polarised intensity and this is extended beyond the core in each of the epochs shown. The core polarisation appears to maintain a fairly constant position angle in the 2007 epochs. In the January 2008 epoch the polarisation in the core appears to fall into two regions, although the polarisation actually in the core maintains the position angle mentioned for the 2007 epochs.

Figure 3.81: August 2007 VLBI Map of 3C273. For polarisation vectors: 1 mas $=7.14 \times 10^{-1}$ Jy/beam.

Map center: RA: 1229 06.700, Dec: +020308.596 (2000.0)
Map peak: $3.27 \mathrm{Jy} /$ beam
Contours \%: $-0.40 .40 .81 .63 .26 .412 .8 \quad 25.6$
Contours \%: 51.2
Beam FWHM: $0.61 \times 0.18$ (mas) at $-18.3^{\circ}$

Figure 3.82: November 2007 VLBI Map of 3C273. For polarisation vectors: 1 mas $=$ $2.50 \times 10^{0} \mathrm{Jy} /$ beam.

Figure 3.83: January 2008 VLBI Map of 3C273. For polarisation vectors: 1 mas $=6.25 \times 10^{-1}$ Jy/beam.

The peak flux for this source changes by a significant amount between each of the epochs. The initial 6.86 Jy rises to 10.7 Jy before the final figure of 8.25 Jy is reached. The overall structure of this source is fairly constant throughout the three epochs. There is very strong levels of polarised intensity in the August 2007 epoch that appears to abruptly rotate between the core and first component. In the same area in November 2007, a rotation of the position angle of polarisation can be seen as well. There is polarisation extending out from the core in January 2008 and the vectors do rotate by a small amount.

Figure 3.84: August 2007 VLBI Map of 3C279. For polarisation vectors: 1 mas $=8.33 \times 10^{-1}$ Jy/beam.

Figure 3.85: November 2007 VLBI Map of 3C279. For polarisation vectors: 1 mas = $2.50 \times 10^{0} \mathrm{Jy} /$ beam.

Figure 3.86: January 2008 VLBI Map of 3C279. For polarisation vectors: 1 mas $=1.00 \times 10^{0}$ Jy/beam.

## 3C345

This is a second source for which there are indications of a helical jet structure in all of the epochs shown. As has been the case for a number of sources, 3C345 reaches its lowest peak flux in the January 2008 epoch. In terms of polarisation, it appears from the polarised intensity maps that it is only the 2007 epochs that harbour any polarisation of significant strength.

Figure 3.87: August 2007 VLBI Map of 3C345. For polarisation vectors: $1 \mathrm{mas}=7.14 \times 10^{-1}$ Jy/beam.

Figure 3.88: November 2007 VLBI Map of 3C345. For polarisation vectors: 1 mas = $1.00 \times 10^{0} \mathrm{Jy} /$ beam.

Map center: RA: 1642 58.810, Dec: +394836.994 (2000.0)
Map peak: $0.819 \mathrm{Jy} /$ beam
Contours \%: $-0.150 .15 \quad 0.30 .61 .22 .44 .8 \quad 9.6$
Contours \%: 19.238 .476 .8
Beam FWHM: $0.249 \times 0.155$ (mas) ot $-29^{\circ}$

Figure 3.89: January 2008 VLBI Map of 3C345. For polarisation vectors: $1 \mathrm{mas}=2.50 \times 10^{-1}$ Jy/beam.

## 3C446

This source brightens by around $1 J y$ between the 2007 epochs shown. Polarisation is present in the core and maintains a fairly steady position angle throughout the three epochs. There is extended polarisation in the August 2007 epoch that may well be real but is weak. The November 2007 polarised intensity map reveals some extended polarisation as well.

Figure 3.90: August 2007 VLBI Map of 3C446. For polarisation vectors: $1 \mathrm{mas}=7.14 \times 10^{-1}$ Jy/beam.

Figure 3.91: November 2007 VLBI Map of 3C446. For polarisation vectors: 1 mas = $1.25 \times 10^{0} \mathrm{Jy} /$ beam.

Figure 3.92: January 2008 VLBI Map of 3C446. For polarisation vectors: $1 \mathrm{mas}=5.00 \times 10^{-1}$ Jy/beam.

## 3C454.3

There is a notable increase in flux between the 2007 epochs ( 5.8 Jy to 7.05 Jy ). There are signs of helical structure in the January 2008 epoch. There is strong polarisation in the core in the 2007 epochs.

Figure 3.93: August 2007 VLBI Map of 3C454.3. For polarisation vectors: 1 mas $=$ $8.33 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.94: November 2007 VLBI Map of 3C454.3. For polarisation vectors: 1 mas $=$ $1.25 \times 10^{0} \mathrm{Jy} /$ beam.

Figure 3.95: January 2008 VLBI Map of 3C454.3. For polarisation vectors: 1 mas = $2.50 \times 10^{-1} \mathrm{Jy} /$ beam.

## BL Lac

There is a drop of roughly $1 J y$ between the November 2007 and January 2008 epochs. The polarised intensity maps for this source show strongly polarised cores across the three epochs shown, with some extended polarisation close to the core in January 2008. The core polarisation position angle is very consistent in all of the epochs shown.

Figure 3.96: August 2007 VLBI Map of BL Lac. For polarisation vectors: $1 \mathrm{mas}=8.33 \times 10^{-1}$ Jy/beam.

Figure 3.97: November 2007 VLBI Map of BL Lac. For polarisation vectors: 1 mas = $8.33 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.98: January 2008 VLBI Map of BL Lac. For polarisation vectors: 1 mas $=5.00 \times 10^{-1}$ Jy/beam.

## CTA102

The peak flux for this source has remained fairly constant through the three epochs shown. The polarised intensity maps for this source indicate significant polarisation in the core for this source across all of the epochs shown.

Figure 3.99: August 2007 VLBI Map of CTA102. For polarisation vectors: 1 mas $=$ $8.33 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.100: November 2007 VLBI Map of CTA102. For polarisation vectors: 1 mas = $6.25 \times 10^{-1} \mathrm{Jy} /$ beam.

Figure 3.101: January 2008 VLBI Map of CTA102. For polarisation vectors: 1 mas = $5.00 \times 10^{-1} \mathrm{Jy} /$ beam.

## OJ287

As can be seen below the VLBI images for this source, the peak flux for this source is higher in November 2007 and January 2008 than it is in August 2007. There appears to be less in the way of extended emission in the January 2008 epoch compared to the others. The maps of polarised intensity show a significantly polarised core in each of the epochs, with some rotation of the position angle of polarisation.

Figure 3.102: August 2007 VLBI Map of OJ287. For polarisation vectors: $1 \mathrm{mas}=5.00 \times 10^{-1}$ Jy/beam.

Figure 3.103: November 2007 VLBI Map of OJ287. For polarisation vectors: 1 mas $=$ $1.92 \times 10^{0} \mathrm{Jy} /$ beam.

Figure 3.104: January 2008 VLBI Map of OJ287. For polarisation vectors: 1 mas $=$ $5.00 \times 10^{-1} \mathrm{Jy} /$ beam.

### 3.4 Component Positions and Kinematics

During the map-making process, 3C273 yielded some interesting results. Its jet trajectories across multiple epochs indicated spiral structures. A good example of this from the above results section can be seen in Figure 3.81. Similar trajectories could be seen in maps of 3C345. For example see Figure 3.87 above.

To investigate this further, model fitting was performed in AIPS (using the task jmfit) on the VLBI maps produced. This allowed positions of individual components to be found.

Given a VLBI map for a source, model fitting with Gaussian profiles can be performed relatively quickly and easily. The brightness distribution across a component in any direction will be fitted as a Gaussian, such that the kind of contour plot seen in a VLBI map of a point source is constructed. The brightness distribution in a small defined area of the VLBI map is obtained, along with some initial guesses at the positions of the components. The initial guess gives approximate values for the peak of the Gaussian. It is possible to obtain the peak of the Gaussian from the brightness distribution of the component. An initial identification of the positions of components along a jet is obtained from examination of the final VLBI map produced for a source. Then the model fitting procedure will fit Gaussian models to obtain major and minor axes for the fitted model of each component. However, it was not instructed to obtain a position angle for the component in most cases for the purposes of avoiding erroneous model fits. A Gaussian profile as shown below is fitted to the brightness distribution along two axes (called $x$ and $y$ for simplicity here):

$$
\begin{equation*}
G(x, y)=\frac{A}{2 \pi \sigma_{x} \sigma_{y}} e^{-\left[\frac{\left(x-x_{0}\right)^{2}}{2 \sigma_{x}^{2}}+\frac{\left(y-y_{0}\right)^{2}}{2 \sigma_{y}^{2}}\right]} \tag{3.1}
\end{equation*}
$$

Thus it is necessary to fit for five parameters. $A$ is a multiplying factor to give the peak flux (without this the equation will be normalised and the peak flux will be unity). Here $\sigma$ is the standard deviation of the function. There will be two parts to this due to the two dimensional Gaussian profile. $x_{0}$ and $y_{0}$ are the positions of the VLBI map centre in right ascension and declination. $x$ and $y$ represent the position of the component centre in the same units.

The Gaussian models are Fourier transformed into the uv plane and need to be fitted to the visibilities therein for a given source. This is achieved by minimisation of the $\chi^{2}$ function.

The peak of the Gaussian model gives the peak flux of the component. The full width half maximum (FWHM) of the Gaussian models yields the axes of an ellipse, hence defining the component's size. Each fitted component should have a blue cross indicating its major and minor axes.

### 3.5 Jet Model Fitting Results

The tables in this section give information on individual components that were model fitted. The main purpose of this was to pinpoint their locations. This was achieved quantitatively via $X$ and $Y$ offsets. It should be noted that these were with respect to the bright-

Figure 3.105: Model fitted components
est point on the VLBI map (usually the core). The results are based upon the VLBI maps that were made by the author in August 2007, November 2007 and January 2008.

Table 3.80: January 2008 Model Fitting Results for OJ287

### 3.6 Kinematic Plots

This section shows plots for individual components. The plots are based upon model fitting data. This is all given in tables for each of the sources in the previous section. Identified components' separation from (what has been judged to be) the core is plotted against observation date. Some of the sources did not have enough in the way of model fitting data to warrant a kinematic plot. Linear fits to the data have been applied. By simple analysis of the gradients of the linear lines, it was possible to extract velocities of the jets from the component behaviours. The linear fits are weighted by the sizes of the errors on each plot, such as to give a better value of the gradient in each case.

Errors in the positions of the components $(\Delta R)$ are calculated via the following formula (Papageorgiou, 2005):

$$
\begin{equation*}
\Delta R=\frac{F W H M}{\left(\frac{S_{p}}{3 \sigma}\right)} \tag{3.2}
\end{equation*}
$$

In this equation, $\sigma$ is the noise level of the VLBI map, FWHM is the full width at half maximum for the major axis of the fitted Gaussian and $S_{p}$ is the peak flux of the component.

Given the uncertainty in identifying components across different epochs, it was decided that the FWHM would be taken as the major axis of the model fitted ellipse. This would yield a more conservative estimate of error for the positional uncertainty. The error for the $x$-offset will equal the error for the $y$-offset for a given component.

Errors were previously calculated from an expression in Reynolds (2002). In most cases the errors were found to give uncertainties in component positions that appeared too small.

## Chapter 4

## Development of a Physical Model

3C273 and 3C345 have been studied in the context of binary black hole models in the past by Kaastra and Roos (1992) and Lobanov and Roland (2005). Such models describe the orbital motion of a black hole around another. Such a system could be responsible for the 'wiggles' observed in some Blazar jets on pc-scales. An alternative is that accretion disc precession could be an intrinsic property of the accretion system (Zensus et al., 2006).

In this chapter I describe how a physical model for helical jet behaviour was developed by myself and A. Papageorgiou, from whom a great deal of input on this model was received.

Given the model fitting that was performed for 3C273 and 3C345, it was necessary to produce a physical model to simulate the helical/ spiral jet trajectories that had been seen.

It is important to make a distinction at this point between model fitting and the production of a physical model. Model fitting serves to make fits to individual components along a jet in order to pinpoint their locations. A physical model will utilise a limited number of set parameters in order to trace out spiral jet trajectories that will hopefully reflect those seen in VLBI maps for 3C273 and 3C345. It was possible to utilise extra epochs of VLBI maps for 3C273 and 3C345 generated by the Blazar Group at Boston University.

The first part of jet modeling was to construct a conic helix in three dimensions using a vector approach with classical kinematics. To begin with, the reference axes shown in Figure 4.1 were used.

In this framework, the jet precesses around the z -axis in the direction shown. The angle $\theta$ remains constant for a single component moving along a linear trajectory. However, $\theta$ rotates around the z -axis with $\hat{I}$ as the vector precesses about the z -axis itself.

### 4.1 The Component Injection Angle

It was assumed at this stage that there was a constant injection of components into the jet. The injection angle (unit) vector is denoted as $\hat{I}$. It has components of $\bar{I}_{x}, \bar{I}_{y}$ and $\bar{I}_{z}$.

Considering a view along the z-axis, it is possible to define another new vector, $\bar{I}_{x y}$. It

Figure 4.1: Definition of Reference Axes
may be considered as the projection of $\hat{I}$ onto the $x-y$ plane.
Here, the angle $\phi$ is defined as the angle between $\bar{I}_{x y}$ and the x-axis, in the x-y plane. From Figure 4.3 it is possible to deduce the relation between $\phi$ and the two components of $\bar{I}_{x y}$ :

$$
\begin{equation*}
\tan \phi=\frac{\left|\bar{I}_{y}\right|}{\left|\bar{I}_{x}\right|} \tag{4.1}
\end{equation*}
$$

Looking at $\bar{I}_{x y}$ and $\hat{I}$ together, it can be seen that $\left|\bar{I}_{x y}\right|=\sin \theta$ because $|\hat{I}|=1$ as can be seen in Figure 4.4.

It is possible to establish another key expression given the equation for a circle of radius, $r$ with $x$-y reference axes $\left(x^{2}+y^{2}=r^{2}\right)$ as shown in Figure 4.3.

$$
\begin{align*}
&\left|\bar{I}_{x}\right|^{2}+\left|\bar{I}_{y}\right|^{2}=\left|\bar{I}_{x y}^{2}\right| \\
&= \sin ^{2} \theta \text { because }\left|\bar{I}_{x y}\right|=\sin (\theta) \text { as stated above. }  \tag{4.2}\\
& \qquad \quad\left|\bar{I}_{y}\right|^{2}=\left|\bar{I}_{x y}\right| \tag{4.3}
\end{align*}
$$

The following equation follows from the definition of $\bar{I}$ :

$$
\begin{equation*}
\left|\bar{I}_{z}\right|=\cos \theta \tag{4.4}
\end{equation*}
$$

It is now necessary to look at how $\phi$ changes as $\hat{I}$ precesses. $\phi$ as a function of time is required. If the time for one rotation of $\hat{I}$ around the $\mathbf{z}$-axis is a period denoted as $P$, it is possible to arrive at the following expression:

Figure 4.2: The Injection Vector

$$
\begin{equation*}
\phi(t)=\frac{2 \pi t}{P} \tag{4.5}
\end{equation*}
$$

Taking $\phi$ to be an angle in radians, it can be seen that this equation is dimensionally correct. Now it is possible to define each of the components of $\hat{I}$ in terms of the parameters introduced so far. Firstly:

$$
\begin{equation*}
\tan \phi=\tan \left(\frac{2 \pi t}{P}\right)=\frac{\left|\bar{I}_{y}\right|}{\left|\bar{I}_{x}\right|} \tag{4.6}
\end{equation*}
$$

Rearranging:

$$
\begin{equation*}
\left|\bar{I}_{y}\right|=\tan \left(\frac{2 \pi t}{P}\right)\left|\bar{I}_{x}\right| \tag{4.7}
\end{equation*}
$$

Squaring this equation and substituting into Equation 4.2 the following expression is obtained once $\left|\bar{I}_{x}\right|$ is factored out:

$$
\begin{equation*}
\left|\bar{I}_{x}\right|^{2}=\frac{\sin ^{2} \theta}{1+\tan ^{2}\left(\frac{2 \pi t}{P}\right)} \tag{4.8}
\end{equation*}
$$

Using the identities $\tan \left(\frac{2 \pi t}{P}\right)=\frac{\sin \left(\frac{2 \pi t}{t}\right)}{\cos \left(\frac{2 \pi}{P}\right)}$ and $\sin ^{2}\left(\frac{2 \pi t}{P}\right)+\cos ^{2}\left(\frac{2 \pi t}{P}\right)=1$ it is possible to finish with a relatively simple expression for $\left|\bar{I}_{x}\right|$ :

$$
\begin{equation*}
\left|\bar{I}_{x}\right|=\sin \theta \cos \left(\frac{2 \pi t}{P}\right) \tag{4.9}
\end{equation*}
$$

Now substituting this into Equation 4.7 it is possible to arrive at a similar equation for $\left|\bar{I}_{y}\right|$ :

Figure 4.3: Definition of $\bar{I}_{x y}$

$$
\begin{equation*}
\left|\bar{I}_{y}\right|=\sin \theta \sin \left(\frac{2 \pi t}{P}\right) \tag{4.10}
\end{equation*}
$$

Thus, it is now possible to show each of the components of the magnitude of $\hat{I}$ :

$$
\begin{equation*}
|\hat{I}|=\left(\sin \theta \cos \left(\frac{2 \pi t}{P}\right), \sin \theta \sin \left(\frac{2 \pi t}{P}\right), \cos \theta\right)=1 \tag{4.11}
\end{equation*}
$$

Therefore:

$$
\begin{equation*}
\hat{I}=\left(\sin \theta \cos \left(\frac{2 \pi t}{P}\right) \hat{I}_{x}, \sin \theta \sin \left(\frac{2 \pi t}{P}\right) \hat{I}_{y},(\cos \theta) \hat{I}_{z}\right) \tag{4.12}
\end{equation*}
$$

It should be appreciated that $\bar{I}_{x}$ and $\bar{I}_{y}$ may be positive or negative depending on the progression of the precessing vector $\bar{I}$.

### 4.2 Component Injection Velocity

If it is assumed that jet components follow linear paths, then the component velocity can be expressed simply as a vector.

$$
\begin{equation*}
\bar{u}=u_{0} \hat{I} \tag{4.13}
\end{equation*}
$$

$u_{0}$ here is the injection velocity for a new component entering the jet. It is a free parameter and is to be set as a constant. In this equation, $\hat{I}$ essentially provides directional information and $u_{0}$ gives the magnitude of the velocity.

Figure 4.4: The Injection Vector and its projection onto the $x-y$ plane
By showing $\hat{I}$ in its fully expanded form, it is possible to express $\bar{u}$ as follows:

$$
\begin{equation*}
\bar{u}=u_{0}\left(\sin \theta \cos \left(\frac{2 \pi t}{P}\right) \hat{I}_{x}, \sin \theta \sin \left(\frac{2 \pi t}{P}\right) \hat{I}_{y},(\cos \theta) \hat{I}_{z}\right) \tag{4.14}
\end{equation*}
$$

### 4.3 Component Displacements

Using simple classical kinematics, that is $s=u t$, it is possible to construct a straightforward expression for a single component. The component is given an initial velocity of $\bar{u}\left(t_{0}\right)$, which allows it to move from $\bar{s}\left(t_{0}\right)$ to $\bar{s}\left(t_{1}\right)$. The equation is the following:

$$
\begin{equation*}
\bar{s}\left(t_{1}\right)=\bar{u}\left(t_{0}\right)\left[t_{1}-t_{0}\right] \tag{4.15}
\end{equation*}
$$

Substituting for $\bar{u}\left(t_{0}\right)$ and expanding $\hat{I}$ with $t=t_{0}$ :

$$
\begin{equation*}
\bar{s}\left(t_{1}\right)=u_{0}\left(\sin \theta \cos \left(\frac{2 \pi t}{P}\right) \hat{I}_{x}, \sin \theta \sin \left(\frac{2 \pi t}{P}\right) \hat{I}_{y}, \cos \theta \hat{I}_{z}\right)\left[t_{1}-t_{0}\right] \tag{4.16}
\end{equation*}
$$

Or in a more compact form:

$$
\begin{equation*}
\bar{s}\left(t_{1}\right)=u_{0} \hat{I}\left(\theta, t_{0}, P\right)\left[t_{1}-t_{0}\right] \tag{4.17}
\end{equation*}
$$

Therefore, this equation gives the displacement of a single component. The time $t_{1}$ is the current injection time or the time of observation, set equal to zero. It is the time at which the new components are injected into the jet flow. The time $t_{0}$ is the time at which an already separated component was introduced into the jet in the past. The parameters to
be set to explore possible jet trajectories (all structures that trace out a conic helix) are $u_{0}$, $\theta, t_{0}$ and $P$.

### 4.4 Plotting Component Displacements

Figure 4.5 shows a portion of the expected jet trajectory from the model as it is up to this point.

Figure 4.5: Expected trajectory for the jet model, showing components injected into the jet at different times

The core is located at the origin of Figure 4.5. Each component could be linked to the core via a straight line to show its individual kinematic motion. The curved line that is shown serves only to link up the components, such that a structure resembling a conic helix begins to take shape.

Components that are more separated from the core were injected into the jet flow further into the past. This demonstrates that as component displacement increases, $t_{0}$ becomes more negative.

Therefore, in the previous equation for a component well separated from the core, $t_{1}=0$ and $t_{0}$ is negative. Thus $t_{1}-t_{0}$ will be positive. But $\hat{I}\left(\theta, t_{0}, P\right)$ should also be considered. $t_{0}$ is negative as has already been stated.

### 4.5 Vector Transformation from Three Dimensions to Two

The model thus far has made a conic helix structure in three dimensions. However, the view that is taken of jets is a projection into two dimensions (onto the sky). These same two dimensions are shown when viewing a VLBI map.

It is necessary to introduce a new vector and two new angles. Figure 4.6 shows all of the new elements that have been added to the modeling.

Figure 4.6: How the new elements of the model fit together with respect to the reference axes
$\bar{s}$ precesses around the z-axis over time. However, it is possible to define a unit vector, $\hat{o}$ that is directed towards the observer. In Figure $4.6 \hat{o}$ is shown at an angle of $\beta$ with respect to $\bar{s}$. $\beta$ should be a small angle, to simulate the situation in the case of Blazars, where the jet is observed to be at a relatively small angle to the line of sight. Since $\hat{o}$ is fixed at a known angle and $\bar{s}$ is a precessing vector, $\beta$ will vary in time when considering multiple components along a jet. For a single component, $\beta$ remains constant because individual components are assumed to travel along linear trajectories for the purposes of this model.

For clarity, the following is a concise summary of the angles present in Figure 4.6:
$\alpha$ The angle between the observer (unit) vector, $\hat{o}$ and the z -axis.
$\beta$ The angle between the observer vector, $\hat{o}$ and the precessing $\bar{s}$ vector.
$\theta$ The angle between the precessing $\bar{s}$ vector and the $z$-axis. It is also the angle between the injection (unit) vector, $\hat{I}$ and the $z$-axis.

The three dimensional jet trajectories resulting from the model so far can be projected onto a two dimensional plane, which is the sky for the observer. At this point, a diagram may be shown to illustrate this transformation more clearly. In Figure 4.7, the shaded region indicates the sky that is visible to the observer. A representation of a possible jet trajectory in three dimensions is shown precessing around the z-axis. Following the direction of the observer vector, $\hat{o}$ it is possible to trace out a view of the jet on the sky, from the perspective of the observer.

Using scalar product notation it is possible to express the following two equations:

$$
\begin{gather*}
\hat{o} \cdot \overline{s_{z}}=\left|\overline{s_{z}}\right| \cos \alpha  \tag{4.18}\\
\hat{o} \cdot \bar{s}=|\bar{s}| \cos \beta \tag{4.19}
\end{gather*}
$$

Figure 4.7: Illustrating how a 3D jet trajectory is transformed onto a 2D plane (the sky)

But at this point, the angle $\beta$ is unknown and will change as $\bar{s}$ precesses. It will be shown that $\beta$ can be expressed using terms that have been established already. However, it is necessary to simplify the analysis by looking for symmetries that arise due to how the model has been set up so far.

Figure 4.8 shows two cones that represent all possible $\hat{o}$ and $\bar{s}$ vectors (given set values of the angles $\alpha$ and $\theta$ respectively). The observer vector $\hat{o}$ is fixed but $\bar{s}$ will precess in time. Two observers may view the same $\bar{s}$ vector differently, but with time the vector will rotate. The two observers will therefore have the same view of the vector but at different times.

There is a conic symmetry that allows placement of the $\hat{o}$ vector in the $x-z$ plane such that $\bar{o}_{y}=0$.

It is possible to write that:

$$
\begin{equation*}
\bar{s}_{\| \hat{o}}=\left|\bar{s}_{\| \hat{o}}\right| \hat{o} \tag{4.20}
\end{equation*}
$$

Also, the following expression can be shown:

$$
\begin{equation*}
\hat{o} \cdot \bar{s}=|\hat{o}||\bar{s}| \cos \beta \tag{4.21}
\end{equation*}
$$

Figure 4.8: Simplification of the model via symmetries

At this point, more definition of $\beta$ is required using the components of the previous scalar product. Therefore:

$$
\begin{equation*}
\left|\bar{o}_{x}\right|\left|\bar{s}_{x}\right|+\left|\bar{o}_{y}\right|\left|\bar{s}_{y}\right|+\left|\bar{o}_{z}\right|\left|\bar{s}_{z}\right|=|\bar{s}| \cos \beta \tag{4.22}
\end{equation*}
$$

Since $\overline{o_{y}}=0$ it is possible to cancel a term here and write:

$$
\begin{equation*}
\cos \beta=\frac{\left|\bar{o}_{x}\right|\left|\bar{s}_{x}\right|+\left|\bar{o}_{z}\right|\left|\bar{s}_{z}\right|}{|\bar{s}|} \tag{4.23}
\end{equation*}
$$

From the simple figure showing $\bar{s}$ and $\hat{o}$ :

$$
\begin{equation*}
\left|\bar{s}_{\| \mid \hat{o}}\right|=|\bar{s}| \cos \beta \tag{4.24}
\end{equation*}
$$

Multiplying through by $\hat{o}$ and using $\bar{s}_{\| \hat{o}}=\left|\bar{s}_{\| \mid \hat{o}}\right| \hat{o}$ it can be shown that $\bar{s}_{\| \hat{o}}=|\bar{s}|(\cos \beta) \hat{o}$.
Similarly, it can be shown that $\bar{s}_{\perp \hat{o}}=|\bar{s}|(\sin \beta) \hat{o}$. Now substituting for $\cos \beta$ and canceling terms:

$$
\begin{equation*}
\bar{s}_{\| \hat{o}}=\hat{o}\left(\left|\bar{o}_{x}\right|\left|\bar{s}_{x}\right|+\left|\bar{o}_{z}\right|\left|\bar{s}_{z}\right|\right) \tag{4.25}
\end{equation*}
$$

Looking at parallel and perpendicular components of $\bar{s}$, vector addition allows that:

$$
\begin{equation*}
\bar{s}_{\perp \hat{o}}=|\bar{s}|-\left[\hat{o}\left(\left|\bar{o}_{x}\right|\left|\bar{s}_{x}\right|+\left|\bar{o}_{z}\right|\left|\bar{s}_{z}\right|\right)\right] \tag{4.26}
\end{equation*}
$$

Figure 4.9:

### 4.6 Obtaining 2D map or sky coordinates

The $x, y$ and $z$ axes have now been defined along with the observer vector $\hat{o}$. Now allow $\bar{s}$ to have sky coordinates such as $\bar{s}(X, Y, Z)$. In making map plots, only two of these dimensions shall be required.
$\hat{o}$ lies in the $\mathrm{x}-\mathrm{z}$ plane so to simplify the analysis it is possible to rotate axes such that $z$ is parallel to $Z$ and $\hat{o}$. In doing this, $y$ is unaffected and runs parallel to $Y . x$ now rotates to become a new axis $X$. The diagram that features the observer's sky also shows the new axes.

It is now possible to define $\bar{s}$ in terms of map or sky coordinates: $\bar{s}(X, Y=y, \hat{o}=Z)$. $\bar{s}(Y)=\bar{s}(y)$ but $\bar{s}(X)$ and $\bar{s}(\hat{o})$ need to be defined. It is now possible to add the new axes to the $\mathrm{x}-\mathrm{z}$ plane.
$\left|\bar{s}_{x}\right|=|\bar{s}| \sin \theta$ and $\left|\bar{s}_{z}\right|=|\bar{s}| \cos \theta$. The precession of $\bar{s}$ is such that $\left|\bar{s}_{z}\right|$ is always positive.

Consider projections of $\bar{s}_{x}$ and $\bar{s}_{z}$ onto the X-axis and term these projections $\bar{s}_{x X}$ and $\bar{s}_{z X}$.
Rotation of the axes is such that the angle between the $x$ and $X$ axes is the angle $\alpha$. It can be seen that $\bar{s}_{z X}=\bar{s}_{z} \sin \alpha$ and $\bar{s}_{x X}=\bar{s}_{x} \cos \alpha$.

It is now possible to express the components of $\bar{s}$ in terms of the map or sky coordinates mentioned above.
$\bar{s}_{X}$ shall be considered first. Note that $\left|\bar{s}_{x X}\right|$ runs along the positive $X$ axis but $\left|\bar{s}_{z X}\right|$ runs along negative $X$. Therefore:

In this equation in the first instance, the negative component along the X -axis has subtracted from the positive component.
$\bar{s}_{Y}$ is a simple case with $\left|\bar{s}_{Y}\right|=\left|\bar{s}_{y}\right|$ such that $\bar{s}_{Y}=\left|\bar{s}_{y}\right| \hat{Y}$.
Finally, $\bar{s}_{\bar{o}}$ needs some definition.

$$
\begin{equation*}
\left|\bar{s}_{o ̂ o}\right|=|\bar{s}| \cos \beta=|\bar{s}| \frac{\left|\bar{o}_{x}\right|\left|\bar{s}_{x}\right|+\left|\bar{o}_{z}\right|\left|\bar{s}_{z}\right|}{|\bar{s}|}=\left|\overline{o_{x}}\right|\left|\bar{s}_{x}\right|+\left|\overline{o_{z}}\right|\left|\bar{s}_{z}\right| \tag{4.28}
\end{equation*}
$$

Here, the earlier definition in Equation 4.23 has been used to remove $\beta$ (time dependent) and replace it with parameters that may be set in the model.

Now it remains to define $\bar{s}_{\hat{o}}$ in terms of angles and components of $s(x, y, z)$ only.
By simple trigonometry it can be seen that $\left|\bar{o}_{x}\right|=\sin \alpha$ and $\left|\bar{o}_{z}\right|=\cos \alpha$ because $|\hat{o}|=1$. Therefore:

$$
\begin{equation*}
\left|\bar{s}_{o}\right|=\left|\bar{s}_{x}\right| \sin \alpha+\left|\bar{s}_{z}\right| \cos \alpha \tag{4.29}
\end{equation*}
$$

It is now possible to arrive at the final expression for this model $(\bar{s}(X, Y)$ may be taken from this for plotting):

$$
\begin{equation*}
\bar{s}(X, Y, \hat{o})=\left[\left(\left|\bar{s}_{x}\right| \cos \alpha-\left|\bar{s}_{z}\right| \sin \alpha\right) X,\left|\bar{s}_{y}\right| Y,\left(\left|\bar{s}_{x}\right| \sin \alpha+\left|\bar{s}_{z}\right| \cos \alpha\right) \hat{o}\right] \tag{4.30}
\end{equation*}
$$

and therefore,

Figure 4.11:

$|\bar{s}(X, Y, \hat{o})|=\left[\left(\left|\bar{s}_{x}\right| \cos \alpha-\left|\bar{s}_{z}\right| \sin \alpha\right),\left|\bar{s}_{y}\right|,\left(\left|\bar{s}_{x}\right| \sin \alpha+\left|\bar{s}_{z}\right| \cos \alpha\right)\right]$

Figure 4.12:

Figure 4.13:

## Chapter 5

## Application of the Physical Model to Results

It was possible to plot out trajectories described by the physical model using the Mathcad computer program. In addition to this I utilised the Levenberg-Marquardt algorithm or LMA to fit the trajectories to my model fitted component positions. The LMA is a very useful curve fitting algorithm that can minimise a function over a space of parameters. The algorithm was first published by Kenneth Levenberg, while working at the Frankford Army Arsenal. It was rediscovered by Donald Marquardt who worked as a statistician at DuPont, an American Chemical Company. See Levenberg (1944) as well as Marquardt (1963) for further information.

Values for the observer angle $\alpha$ for 3C273 and 3C345 have been previously reported (Jorstad et al., 2005) as 6.1 and 2.7 degrees respectively. To simplify matters, these values were incorporated as fixed parameters.

Weighted averages of the Lorentz factor for the sources were also presented in Jorstad et al. (2005). These were 10.6 and 18.7 for 3C273 and 3C345 respectively. From these values it was possible to calculate velocities that could serve as $u_{0}$ for the two sources. It is assumed that components are injected, and propagate down the jets at a constant velocity. The calculated velocities were 0.996 c for 3 C 273 and 0.999 c for 3C345.

It is worth describing the methods employed in deriving some of the parameters in Jorstad et al. (2005). The Lorentz factors and viewing angles in this work were solutions of a system that combined two equations (one for the apparent speed of the knots studied and the other for their Doppler factors) for a knot having a measured apparent speed and a variability Doppler factor derived via the following equation:

$$
\begin{equation*}
\delta_{v a r}=\frac{s D}{c \Delta t_{v a r}(1+z)} \tag{5.1}
\end{equation*}
$$

Here $D$ is the luminosity distance, $s$ is the angular size of the component and $\Delta t_{v a r}$ is the timescale of variability for each superluminal component.

The two equations that were combined are as follows:

$$
\begin{equation*}
\beta_{a p p}=\beta \sin \theta_{0}\left(1-\beta \cos \theta_{0}\right)^{-1} \tag{5.2}
\end{equation*}
$$

In this case, $\beta$ is the intrinsic velocity of a component and $\theta_{0}$ is the angle between the jet trajectory and the line of sight. There is calculation of proper motions for jet components in the work.

$$
\begin{equation*}
\delta=\left[\Gamma\left(1-\beta \cos \theta_{0}\right)\right]^{-1} \tag{5.3}
\end{equation*}
$$

Where $\Gamma$ is the Lorentz factor of the knot.
For their work with jet velocities, Jorstad et al. (2005) adopt an inhomogeneous Friedmann-Lemaître-Robertson-Walker cosmology with $\Omega_{m}=0.3, \Omega_{\Lambda}=0.7$ and Hubble constant $H_{0}=70 \mathrm{kms}^{-1} \mathrm{Mpc}^{-1}$.

Offset subtractions were made to the model fitting results such that the origin of the plots would be the (presumed) core of each jet image.

It was possible to rotate the model fitting results for 3C273 and 3C345 so as to remove angular offsets. The rotation matrix used is shown below. It rotated each of the model fitted coordinates in an anticlockwise direction.

$$
\left[\begin{array}{cc}
\cos \theta & -\sin \theta \\
\sin \theta & \cos \theta
\end{array}\right]
$$

In the sections that follow, I plot the component positions either side of the jet axis against time for 3C273 and 3C345. The component of displacement away from the jet core parallel to the jet axis will be assumed to increase at a constant rate.

The graphs indicate the application of the physical model to my model fitted data.

### 5.1 3C273 Plots

## 3C273 - August 2007

Figure 5.1: 3C273 in August 2007. A graph showing the model fitting results along with a fitted physical model. Parameters obtained from the fitting were $\theta=2.793^{\circ}$ and $P=$ 47.502 years.

## 3C273 - November 2007

Figure 5.2: 3C273 in November 2007. A graph showing the model fitting results along with a fitted physical model. Parameters obtained from the fitting were $\theta=3.346^{\circ}$ and $P=48.119$ years.

## 3C273 - January 2008

Figure 5.3: 3C273 in January 2008. A graph showing the model fitting results along with a fitted physical model. Parameters obtained from the fitting were $\theta=2.764^{\circ}$ and $P=$ 117.861 years.

### 5.2 3C345 Plots

## $3 C 345$ - August 2007

Figure 5.4: 3C345 in August 2007. A graph showing the model fitting results along with a fitted physical model. Parameters obtained from the fitting were $\theta=3.691^{\circ}$ and $P=$ 43.880 years.

## 3C345-November 2007

Figure 5.5: 3C345 in November 2007. A graph showing the model fitting results along with a fitted physical model. Parameters obtained from the fitting were $\theta=2.603^{\circ}$ and $P=44.802$ years.

## 3C345-January 2008

Figure 5.6: 3C345 in January 2008. A graph showing the model fitting results along with a fitted physical model. Parameters obtained from the fitting were $\theta=1.262^{\circ}$ and $P=$ 56.752 years.

## Chapter 6

## Principle Results of Kinematic Study

The conclusions here are split into two main parts. These are the calculated jet velocities and the outcomes from the fitting of a physical model to maps generated for 3C273 and 3C345.

### 6.1 Jet Velocities

It has been possible to calculate jet velocities for 15 Blazar sources. Linear fits were made to the kinematic plots that were generated for selected sources. For many sources, it was not worthwhile making such plots since there was simply not enough data to work with. The final results are shown in tables for each source. Data is sorted in terms of the velocities derived. Jet velocities are shown firstly as proper motions (mas/yr) and are then converted into apparent superluminal (or subluminal) velocities via the following equation (Cohen, 2009):

$$
\begin{equation*}
v=\mu D(1+z) \tag{6.1}
\end{equation*}
$$

Here $v$ is the apparent velocity and $\mu$ is the proper motion of a component. $D$ is the luminosity distance to the source and $z$ is its redshift.

Luminosity distances are incorporated assuming $H_{0}=71 \mathrm{~km} / \mathrm{s} / \mathrm{Mpc}, \Omega_{\Lambda}=0.73$ and $\Omega_{m}=0.27$.

The luminosity distances and redshifts of sources were taken from data made publically available on the MOJAVE ( 2 cm VLBI survey) database which may be viewed at www.physics.purdue.edu/astro/MOJAVE. The database is maintained by the MOJAVE team (Lister et al., 2009).

In some cases the proper motion error (and therefore the apparent velocity error) is marked with N/A. Since the errors were the uncertainties in the linear fits to the kinematic plots, this is a reflection of having only two points to fit to for some components.

| Component | Internal Proper Motion (mas/yr) | Apparent Transverse Velocity (c) |
| :---: | :---: | :---: |
| 1 | $1.72 \pm 0.0172$ | $79.90 \pm 0.80$ |
| 2 | $2.67 \pm 0.4180$ | $124.03 \pm 19.42$ |

Table 6.1: Component Kinematics for 0336-019. Maximum jet velocity as quoted from the MOJAVE database: $22.36 c$.

| Component | Internal Proper Motion (mas/yr) | Apparent Transverse Velocity (c) |
| :---: | :---: | :---: |
| 1 | $0.146 \pm 0.0601$ | $7.16 \pm 2.95$ |

Table 6.16: Final Parameter Values from the Application of a Physical Model to Model Fitting Data. $\bar{\theta}$ and $\bar{P}$ are average values (standard error included) of $\theta$ and $P$ for each source.

### 6.2 Application of a Physical Model to Model Fitting Results

Table 6.16 gives a summary of the parameters obtained from the physical model application. Values for $\alpha$ and $u_{0}$ are taken from, or calculated from work presented by Jorstad et al. (2005).

As a reminder of the definitions for the parameters in this table, $\theta$ is essentially the jet half angle, $\alpha$ is the angle between the observer vector and the z -axis, which may be taken to be the jet axis in the physical model that has been derived in this work. $P$ is the period of precession of the central engine (causing non-linear jet structure). Finally, $u_{0}$ is the component injection velocity.

## Chapter 7

## Discussion, Conclusions and Further Work

In studying astrophysical jets, one method of analysis comes from looking at the evolution of flux density and EVPA with time. Such work can yield information on new components that may or may not be in the process of being injected into the jet flow for a source. The observational indications of a new component injection are a significant increase in flux density for the source (due to the added flux of the new component) and a change in EVPA. In the optically thick core, it would be expected that the EVPA would be roughly perpendicular to the jet axis. Study of the Blazar OJ287 by D'Arcangelo et al. (2009) supports such an idea. In this work, a spine-sheath model is proposed for OJ287. In the so-called transition region between the spine and sheath in this model, velocity shear is responsible for the orientation of the core EVPA.

There was some attempt to look at the fluxes of the sources analysed in this work. However, no significant jumps in flux were noted. A more thorough look at the fluxes of the sources analysed may be a worthy avenue of possible further work. This thesis has been concerned more with the kinematics of imaged jet structures.

### 7.1 Component Velocities

In terms of the component velocities calculated, there are some values that appear to be very large. There are also negative velocities.

The main issue with this analysis is the correct identification of components over several epochs. This difficulty has been pointed out by Jorstad et al. (2001). Misidentification of components could have a large impact on the component velocities that have been derived.

Misidentification of components might well explain some of the component velocities that appear to be far too high. Where possible, it is worth looking at such results again and comparing them to proper motions of components derived from a previous study (Jorstad et al., 2001). This work shall be referred to as J-2001 for the remainder of this section. Comparison with previous results will allow an appreciation of whether or not components in certain sources have reached the velocities quoted in this work.

For 0336-019, J-2001 reports proper motion values of 0.18 and 0.42 mas/ yr. These values are significantly lower than those found in this work. In the case of $1611+343 \mathrm{~J}-2001$ gives component proper motion values of $0.57,0.49,0.18$ and 0.31 mas $/ \mathrm{yr}$. Two of the values derived in this work for the same source are closer to unity in terms of proper motion. This is a notable difference. 1730-130 has 0.28 mas $/ \mathrm{yr}$ as it's highest value in $\mathrm{J}-2001$. This is much lower than the value of 1.10 mas/ yr that has been found for component 3 in the source. For 3C279, proper motions of around 1 mas/ yr and above have been found in this work. 0.31 mas/yr is the highest value given in J-2001 for this source. 3C454.3 is shown with component proper motions of $0.14,0.34$ and 0.53 mas/yr in J-2001. However, in this work, values approaching 2 mas/yr are found. Finally, for CTA102 in J-2001 there are proper motions for components between 0.2 and 0.4 mas/yr. However, in this work a component proper motion of $0.829 \mathrm{mas} / \mathrm{yr}$ has been calculated.

It is not true that every source analysed in this work has proper motions that are questionably large. This seems to rule out any kind of systematic error in the analysis.

Negative velocities might possibly be explained by motion of the (presumed) core at 43 GHz . If a component distance from the core is calculated in one epoch and then the core appears to move downstream such that the distance is reduced, the overall effect would be that the component would appear to be moving toward the core.

### 7.2 Fitting the Physical Model

The outcomes of the fitting were mixed in terms of success. There are cases where the trajectories plotted do not really reflect the data for a certain source and epoch. However, there is some good agreement. Figure 5.2 demonstrates some reasonable correlation for 3C273. Also, there is a fairly good fit in Figure 5.4.

To perform the application of the physical model more successfully more observed and model fitted components would be helpful for both 3C273 and 3C345. This would give a better impression of how well a model fits the observed component positions.

The limit is the VLBA's ability to resolve components. Observations at higher frequency would be a worthwhile study. It may be found that a component at 43 GHz may be resolved into more than one component at higher frequency.

This work indicates that with more model fitted components, it could be possible to analyse and understand key characteristics of non-linear Blazar jets. The basic method to follow is:

1. Produce VLBI images of a sample of Blazar jets and look for non-linear structures. The sample should be as big as possible to maximise the chances of finding nonlinear jets.
2. Model fit as many components as possible in the jets demonstrating non-linear structure.
3. Develop a physical model to simulate the jet behaviour.
4. Fit the physical model to the model fitted data.
5. Pinpoint important characteristics of the jet system, for example the period of jet precession.

[^0]:    ${ }^{1}$ If $R$ is taken to be a measure of distance along a jet's axis, then it may be shown that $B_{\perp} \propto R^{-1}$ whereas $B_{\|} \propto R^{-2}$. Here $B_{\perp}$ and $B_{\|}$are components of the magnetic field lines that are perpendicular and parallel to the jet axis respectively.

[^1]:    ${ }^{2} a=1$ for a magnetic field perpendicular to the jet axis whereas $a=2$ for parallel magnetic fields.

[^2]:    ${ }^{1}$ Intermediate frequencies allow the interferometers to observe a range of frequencies. For the observations in this work there were four IFs in operation at and just above 43 GHz . IFs are utilised in VLBI in order to increase the bandwidth of observation. This in turn yields greater sensitivity.
